Anemia is the most common hematologic condition affecting elderly patients; with each successive decade of life, the incidence of anemia increases. Anemia frequently results from iron deficiency (in the case of blood loss) or from a nutritional deficiency, particularly folate or B12 deficiency or protein-calorie malnutrition; it may also result from inflammation or chronic disease. Management of the disorder varies depending on the etiology. Therefore, it is important to identify the cause of the anemia rather than to consider it an inevitable consequence of aging. Elderly people with concurrent cardiac or pulmonary problems may not tolerate anemia very well, and a prompt, thorough evaluation is warranted.

**Assessment and Diagnostic Findings**

Many hematologic conditions cause few symptoms. Therefore, the use of extensive laboratory tests is often required to diagnose a hematologic disorder. For most hematologic conditions, continued monitoring via specific blood tests is required because it is very important to assess for changes in test results over time.

**HEMATOLOGIC STUDIES**

The most common tests used are the complete blood count (CBC) and the peripheral blood smear (Table 33–2). The CBC identifies the total number of blood cells (WBCs, RBCs, and platelets) as well as the hemoglobin, hematocrit (percentage of blood consisting of RBCs), and RBC indices. Because cellular morphology (shape and appearance of the cells) is particularly important in most hematologic disorders, the physician needs to examine the blood cells involved. This process is referred to as the manual examination of the peripheral smear, which may be part of the CBC. In this test, a drop of blood is spread on a glass slide, stained, and examined under a microscope. The shape and size of the RBCs and platelets as well as the actual appearance of the WBCs provides useful information in identifying hematologic conditions. Blood for the CBC is typically obtained by venipuncture.

**BONE MARROW ASPIRATION AND BIOPSY**

The bone marrow aspiration and biopsy are crucial when additional information is needed to assess how an individual’s blood cells are being formed and to assess the quantity and quality of each type of cell produced within the marrow. These tests are also used to document infection or tumor within the marrow.

Normal bone marrow is in a semifluid state and can be aspirated through a special large needle. In adults, bone marrow is usually aspirated from the iliac crest and occasionally from the sternum. The aspirate provides only a sample of cells. Aspirate alone may be adequate for evaluating certain conditions, such as anemia. However, when more information is required, a biopsy is also performed. Biopsy samples are taken from the posterior iliac crest; occasionally, an anterior approach is required. A marrow biopsy shows the architecture of the bone marrow as well as its degree of cellularity.

Most patients need no more preparation than a careful explanation of the procedure, but for some very anxious patients, an antianxiety agent may be useful. It is always important for the physician or nurse to describe and explain to the patient the procedure and the sensations that will be experienced. The risks, benefits, and alternatives are also discussed. A signed informed consent is needed before the procedure is performed.

Before aspiration, the skin is cleansed as for any minor surgery, using aseptic technique. Then a small area is anesthetized with a local anesthetic through the skin and subcutaneous tissue to the periosteum of the bone. It is not possible to anesthetize the bone itself. The bone marrow needle is introduced with a styllet in place. When the needle is felt to go through the outer cortex of bone and enter the marrow cavity, the styllet is removed, a syringe is attached, and a small volume (0.5 mL) of blood and marrow is aspirated. Patients typically feel a pressure sensation as the needle is advanced into position. The actual aspiration always causes sharp but brief pain, resulting from the suction exerted as the marrow is aspirated into the syringe; the patient should be forewarned about this. Taking deep breaths or using relaxation techniques often helps ease the discomfort.

If a bone marrow biopsy is necessary, it is best performed after the aspiration and in a slightly different location, because the marrow structure may be altered after aspiration. A special biopsy needle is used. Because these needles are large, the skin is punctured first with a surgical blade to make a 3- or 4-mm incision. The biopsy needle is advanced well into the marrow cavity. When the needle is properly positioned, a portion of marrow is cored out, using a twisting or gentle rocking motion to free the sample and permit its removal within the biopsy needle. Patients feel a pressure sensation but should not feel actual pain. The nurse should instruct the patient to inform the physician if pain occurs so that additional anesthetic can be administered.

The major hazard of either bone marrow aspiration or biopsy is a slight risk of bleeding and infection. The bleeding risk is somewhat increased if the patient’s platelet count is low or if the patient has been taking a medication (eg, aspirin) that alters platelet func-

<thead>
<tr>
<th>TEST</th>
<th>NORMAL RANGE</th>
<th>DESCRIPTION</th>
<th>INDICATIONS/COMMENTS</th>
</tr>
</thead>
<tbody>
<tr>
<td>Complete blood count (CBC)</td>
<td></td>
<td>General survey of bone marrow function; evaluates all three cell lines (WBCs, RBCs, platelets)</td>
<td>Important to note changes over time; many hematologic conditions show changes in CBC long before patient becomes symptomatic</td>
</tr>
<tr>
<td>Red blood cells (RBCs)</td>
<td>M: 4.7–6.1 × 10^6 F: 4.2–5.4 × 10^6</td>
<td>Carries hemoglobin; survival time, 120 days</td>
<td></td>
</tr>
<tr>
<td>Hemoglobin (Hgb)</td>
<td>M: 13.5–17.5 g/dL F: 11.5–15.5 g/dL</td>
<td>Delivers O₂ through circulation to body tissues and returns CO₂ from tissues to lungs</td>
<td>Decreased in anemia; increased in polycythemia</td>
</tr>
<tr>
<td>Hematocrit (Hct)</td>
<td>M: 40–52% F: 36–48%</td>
<td>Indicates relative proportions of plasma and RBCs (volume of RBCs/L whole blood)</td>
<td>Usually three times the Hgb</td>
</tr>
<tr>
<td>Mean corpuscular volume (MCV)</td>
<td>81–96 µm³</td>
<td>Indicates size of RBCs; very useful in differentiating types of anemia</td>
<td>If &lt; 80, cells are microcytic; if &gt; 100, cells are macrocytic</td>
</tr>
<tr>
<td>Mean corpuscular hemoglobin concentration (MCHC)</td>
<td>33–36 g/dL</td>
<td>Average concentration of Hgb in RBCs; independent of cell size</td>
<td></td>
</tr>
<tr>
<td>Red cell distribution width (RDW)</td>
<td>11–14.5%</td>
<td>Measures degree of variation in size of RBCs</td>
<td></td>
</tr>
<tr>
<td>Reticulocyte count</td>
<td>0.5–1.5%</td>
<td>Measure of marrow production of erythrocytes; 1% of RBC mass is produced daily (to replace the 1% of old cells that die)</td>
<td>Indicates marrow’s response to anemia (when anemia is present, reticulocyte level should rise)</td>
</tr>
<tr>
<td>Platelets</td>
<td>150,000–400,000/mm³</td>
<td>Total number of platelets in circulation; average life span, 7–10 days</td>
<td>Thrombocytopenia; &lt; 20,000/mm³, serious; &lt; 10,000/mm³, potentially life-threatening</td>
</tr>
<tr>
<td>White blood cells (WBCs)</td>
<td>4,500–11,000/mm³</td>
<td>Total WBC count</td>
<td></td>
</tr>
<tr>
<td>Differential</td>
<td></td>
<td>% of cell type × total WBC = absolute number of that cell type</td>
<td>Left shift: bone marrow ↑ production of WBCs; more immature forms released into the bloodstream</td>
</tr>
<tr>
<td>Prothrombin time (PT)</td>
<td>Varies (compare with control), 11–12.5 sec</td>
<td>Measure time elapsed until clot forms; measures extrinsic and common pathways</td>
<td>Increased in liver disease, disseminated intravascular coagulation (DIC), obstructive biliary disease, clotting factor depletion, warfarin (Coumadin) use</td>
</tr>
<tr>
<td>International normalized ratio (INR)</td>
<td>1.0</td>
<td>Standard warfarin (Coumadin) treatment, 2.0–3.0 INR; high-dose warfarin (Coumadin) treatment, 3.0–4.5 INR</td>
<td>Increased with anticoagulant excess and conditions that cause increased PT; decreased with insufficient anticoagulant and conditions that cause decreased PT</td>
</tr>
<tr>
<td>Partial thromboplastin time (PTT)</td>
<td>Varies (compare with control): 25–35 sec</td>
<td>Surface active agent added to plasma; measures time elapsed until clot forms; measures intrinsic and common pathways</td>
<td>Increased in clotting factor depletion, DIC, liver disease, biliary obstruction, circulating anticoagulants (heparin)</td>
</tr>
<tr>
<td>Thrombin time (TT)</td>
<td>Varies (compare with control), 8–11 sec</td>
<td>Tests conversion of fibrinogen to fibrin</td>
<td>Time to clot is inversely proportional to fibrinogen level</td>
</tr>
<tr>
<td>Fibrinogen</td>
<td>170–340 mg/100 mL</td>
<td>Measurement of fibrinogen concentration within plasma available for conversion to fibrin clot</td>
<td>Decreased in bleeding disorders, pregnancy, malignancy, inflammatory disease</td>
</tr>
<tr>
<td>D-dimer</td>
<td>0–0.5 µg/mL</td>
<td>Measures the amount of fragments of fibrin when it is lysed (broken down); useful for distinguishing fibrinolysis from fibrinogenolysis</td>
<td>Increased with fibrinolytic activity, rheumatoid arthritis, ovarian cancer (with increased CA 125)</td>
</tr>

(continued)
tion. After the marrow sample is obtained, pressure is applied to the site for several minutes. The site is then covered with a sterile dressing. Most patients have no discomfort after a bone marrow aspiration, but the site of a biopsy may ache for 1 or 2 days. Warm tub baths and use of a mild analgesic (eg, acetaminophen) may be useful. Aspirin-containing analgesics should be avoided because they can aggravate or potentiate any bleeding that may occur.

Management of Hematologic Disorders

Commonly encountered blood disorders are anemia, polycythemia, leukopenia and neutropenia, leukocytosis, lymphoma, myeloma, leukemia, and various bleeding and coagulation disorders. Nursing management of patients with these disorders requires skillful assessment and monitoring as well as meticulous care and teaching to prevent deterioration and complications.

ANEMIA

Anemia, per se, is not a specific disease state but a sign of an underlying disorder. It is by far the most common hematologic condition. Anemia, a condition in which the hemoglobin concentration is lower than normal, reflects the presence of fewer than normal RBCs within the circulation. As a result, the amount of oxygen delivered to body tissues is also diminished.

There are many different kinds of anemia (Table 33-3), but all can be classified into three broad etiologic categories:

- Loss of RBCs—occurs with bleeding, potentially from any major source, such as the gastrointestinal tract, the uterus, the nose, or a wound
- Decreased production of RBCs—can be caused by a deficiency in cofactors (including folic acid, vitamin B12, and iron) required for erythropoiesis; RBC production may also be reduced if the bone marrow is suppressed (eg, by tumor, medications, toxins) or is inadequately stimulated because of a lack of erythropoietin (as occurs in chronic renal disease).
- Increased destruction of RBCs—may occur because of an overactive RES (including hypersplenism) or because the bone marrow produces abnormal RBCs that are then destroyed by the RES (eg, sickle cell anemia).

A conclusion as to whether the anemia is caused by destruction or by inadequate production of RBCs usually can be reached on the basis of the following factors:

- The marrow’s ability to respond to the decreased RBCs (as evidenced by an increased reticulocyte count in the circulating blood)
- The degree to which young RBCs proliferate in the bone marrow and the manner in which they mature (as observed on bone marrow biopsy)
- The presence or absence of end products of RBC destruction within the circulation (eg, increased bilirubin level, decreased haptoglobin level)
dehydrogenase [G-6-PD] deficiency) or within the plasma (eg, immune hemolytic anemias), or from direct injury to the RBC within the circulation (eg, hemolysis caused by mechanical heart valve). Chart 33-1 identifies the causes of hemolytic anemia.

### Clinical Manifestations

Aside from the severity of the anemia itself, several factors influence the development of anemia-associated symptoms:

- The speed with which the anemia has developed
- The duration of the anemia (ie, its chronicity)
- The metabolic requirements of the individual
- Other concurrent disorders or disabilities (eg, cardiovascular disease)
- Special complications or concomitant features of the condition that produced the anemia

In general, the more rapidly an anemia develops, the more severe its symptoms. An otherwise healthy person can often tolerate as much as a 50% gradual reduction in hemoglobin without pronounced symptoms or significant incapacity, whereas the rapid loss of as little as 30% may precipitate profound vascular collapse in the same individual. A person who has been anemic for a very long time, with hemoglobin levels between 9 and 11 g/dL, usually has few or no symptoms other than slight tachycardia on exertion and fatigue.

### Classification of Anemias

Anemia may be classified in several ways. The physiologic approach is to determine whether the deficiency in RBCs is caused by a defect in their production (hypoproliferative anemia), by their destruction (hemolytic anemia), or by their loss (bleeding).

In the hypoproliferative anemias, RBCs usually survive normally, but the marrow cannot produce adequate numbers of these cells. The decreased production is reflected in a low reticulocyte count; the decreased production is reflected in a low reticulocyte count, as the bone marrow responds to the loss of RBCs. The released hemoglobin is converted in large part to bilirubin; therefore, the bilirubin concentration rises. Hemolysis can result from an abnormality within the RBC itself (eg, sickle cell anemia, glucose-6-phosphate dehydrogenase (G-6-PD) deficiency) or within the plasma (eg, immune hemolytic anemias), or from direct injury to the RBC within the circulation (eg, hemolysis caused by mechanical heart valve). Chart 33-1 identifies the causes of hemolytic anemia.
Patients who customarily are very active or who have significant demands on their lives (eg, a single, working mother of small children) are more likely to have symptoms, and those symptoms are more likely to be pronounced than in a more sedentary person. A patient with hypothyroidism with decreased oxygen needs may be completely asymptomatic, without tachycardia or increased cardiac output, at a hemoglobin level of 10 g/dL. Similarly, patients with coexistent cardiac, vascular, or pulmonary disease may develop more pronounced symptoms of anemia (eg, dyspnea, chest pain, muscle pain or cramping) at a higher hemoglobin level than those without these concurrent health problems.

Finally, some anemic disorders are complicated by various other abnormalities that do not result from the anemia but are inherently associated with these particular diseases. These abnormalities may give rise to symptoms that completely overshadow those of the anemia, as in the painful crises of sickle cell anemia.

**Assessment and Diagnostic Findings**

A variety of hematologic studies are performed to determine the type and cause of the anemia. In an initial evaluation, the hemoglobin, hematocrit, reticulocyte count, and RBC indices, particularly the mean corpuscular volume (MCV), are particularly useful. Iron studies (serum iron level, total iron-binding capacity [TIBC], percent saturation, and ferritin), as well as serum vitamin B₁₂ and folate levels, are also frequently obtained. Other tests include haptoglobin and erythropoietin levels. The remaining CBC values are useful in determining whether the anemia is an isolated problem or part of another hematologic condition, such as leukemia or myelodysplastic syndrome (MDS). Bone marrow aspiration may be performed. In addition, other diagnostic studies may be performed to determine the presence of underlying chronic illness, such as malignancy, and the source of any blood loss, such as polyps or ulcers within the gastrointestinal tract.

**Complications**

General complications of severe anemia include heart failure, paresthesias, and confusion. At any given level of anemia, patients with underlying heart disease are far more likely to have angina or symptoms of heart failure than those without heart disease. Complications associated with specific types of anemia are included in the description of each type.

**Medical Management**

Management of anemia is directed toward correcting or controlling the cause of the anemia; if the anemia is severe, the RBCs that are lost or destroyed may be replaced with a transfusion of packed RBCs (PRBCs). The management of the various types of anemia is covered in the discussions that follow.

**NURSING PROCESS: THE PATIENT WITH ANEMIA**

**Assessment**

The health history and physical examination provide important data about the type of anemia involved, the extent and type of symptoms it produces, and the impact of those symptoms on the patient’s life. Weakness, fatigue, and general malaise are common, as are pallor of the skin and mucous membranes (sclera, oral mucosa).

Jaundice may be present in patients with megaloblastic anemia or hemolytic anemia. The tongue may be smooth and red (in iron deficiency anemia) or beefy red and sore (in megaloblastic anemia); the corners of the mouth may be ulcerated (angular cheilosis) in both types of anemia. Individuals with iron deficiency anemia may crave ice, starch, or dirt (known as pica); their nails may be brittle, ridged, and concave.

The health history should include a medication history, because some medications can depress bone marrow activity or interfere with folate metabolism. An accurate history of alcohol intake, including the amount and duration, should be obtained. Family history is important, because certain anemias are inherited. Athletic endeavors should be assessed, because extreme exercise can decrease erythropoiesis and RBC survival in some athletes.

A nutritional assessment is important, because it may indicate deficiencies in essential nutrients such as iron, vitamin B₁₂, and folic acid. Children of indigent families may be at higher risk for anemia because of nutritional deficiencies. Strict vegetarians are also at risk for megaloblastic types of anemia if they do not supplement their diet with vitamin B₁₂.

Cardiac status should be carefully assessed. When the hemoglobin level is low, the heart attempts to compensate by pumping faster and harder in an effort to deliver more blood to hypoxic tissue. This increased cardiac workload can result in such symptoms as tachycardia, palpitations, dyspnea, dizziness, orthopnea, and exertional dyspnea. Heart failure may eventually develop, as evidenced by an enlarged heart (cardiomegaly) and liver (hepatomegaly) and by peripheral edema.

Assessment of the gastrointestinal system may disclose complaints of nausea, vomiting (with specific questions as to the appearance of any emesis [eg, looks like “coffee grounds”]), melena or dark stools, diarrhea, anorexia, and glossitis (inflammation of the tongue). Stools should be tested for occult blood. Women should be questioned about their menstrual periods (eg, excessive menstrual flow, other vaginal bleeding) and the use of iron supplements during pregnancy.

The neurologic examination is also important because of the effect of pernicious anemia on the central and peripheral nervous systems. Assessment should include the presence and extent of peripheral numbness and paresthesias, ataxia, poor coordination, and confusion. Finally, it is important to monitor relevant laboratory test results and to note any changes over time.

**Diagnosis**

**NURSING DIAGNOSES**

Based on the assessment data, major nursing diagnoses for the anemic patient may include:

- Activity intolerance related to weakness, fatigue, and general malaise
- Imbalanced nutrition, less than body requirements, related to inadequate intake of essential nutrients
- Ineffective tissue perfusion related to inadequate blood volume or hematocrit
- Noncompliance with prescribed therapy

**COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS**

Based on the assessment data, potential complications that may develop include:

- Heart failure
- Paresthesias
- Confusion
Planning and Goals

The major goals for the patient may include increased tolerance of normal activity, attainment or maintenance of adequate nutrition, maintenance of adequate tissue perfusion, compliance with prescribed therapy, and absence of complications.

Nursing Interventions

MANAGING FATIGUE
The most frequent symptom and complication of anemia is fatigue. This distressing symptom is too often minimized by health care providers. Fatigue is often the symptom that has the greater negative impact on the individual's level of functioning and consequent quality of life. Patients describe the fatigue from anemia as oppressive. Fatigue can be significant, yet the anemia may not be severe enough to warrant transfusion. Fatigue can interfere with an individual's ability to work, both inside and outside the home. It can harm relationships with family and friends. Patients often lose interest in hobbies and activities, including sexual activity. The distress from fatigue is often related to an individual's responsibilities and life demands as well as the amount of assistance and support received from others.

Nursing interventions can focus on assisting the patient to prioritize activities and to establish a balance between activity and rest that is realistic and feasible from the patient's perspective. Patients with chronic anemia need to maintain some physical activity and exercise to prevent the deconditioning that results from inactivity.

MAINTAINING ADEQUATE NUTRITION

Inadequate intake of essential nutrients, such as iron, vitamin B₁₂, folic acid, and protein can cause some anemias. The symptoms associated with anemia (eg, fatigue, anorexia) can in turn interfere with maintaining adequate nutrition. A healthy diet should be encouraged. Because alcohol interferes with the utilization of essential nutrients, the nurse should advise the patient to avoid alcoholic beverages or to limit their intake and should provide the rationale for this recommendation. Dietary teaching sessions should be individualized, including cultural aspects related to food preferences and food preparation. The involvement of family members enhances compliance with dietary recommendations. Dietary supplements (eg, vitamins, iron, folate, protein) may be prescribed as well.

Equally important, the patient and family must understand the role of nutritional supplements in the proper context, because many forms of anemia are not the result of a nutritional deficiency. In such cases, excessive intake of nutritional supplements will not improve the anemia. A potential problem in individuals with chronic transfusion requirements occurs with the indiscriminate use of iron. Unless an aggressive program of chelation therapy is implemented, these individuals are at risk for iron overload from their transfusions alone. The addition of an iron supplement only exacerbates the situation.

MAINTAINING ADEQUATE PERFUSION

Patients with acute blood loss or severe hemolysis may have decreased tissue perfusion from decreased blood volume or reduced circulating RBCs (decreased hematocrit). Lost volume is replaced with transfusions or intravenous fluids, based on the symptoms and the laboratory findings. Supplemental oxygen may be necessary, but it is rarely needed on a long-term basis unless there is underlying severe cardiac or pulmonary disease as well. The nurse monitors vital signs closely; other medica-

tions, such as antihypertensive agents, may need to be adjusted or withheld.

PROMOTING COMPLIANCE WITH PRESCRIBED THERAPY

For patients with anemia, medications or nutritional supplements are often prescribed to alleviate or correct the condition. These patients need to understand the purpose of the medication, how to take the medication and over what time period, and how to manage any side effects of therapy. To enhance compliance, the nurse can assist patients in developing ways to incorporate the therapeutic plan into their lives, rather than merely giving the patient a list of instructions. For example, many patients have difficulty taking iron supplements because of related gastrointestinal effects. Rather than seeking assistance from a health care provider in managing the problem, some of these patients simply stop taking the iron.

Abruptly stopping some medications can have serious consequences, as in the case of high-dose corticosteroids to manage hemolytic anemias. Some medications, such as growth factors, are extremely expensive. Patients receiving these medications may need assistance with obtaining needed insurance coverage or with exploring alternatives for obtaining these medications.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

A significant complication of anemia is heart failure from chronic diminished blood volume and the heart's compensatory effort to increase cardiac output. Patients with anemia should be assessed for signs and symptoms of heart failure. A serial record of body weights can be more useful than a record of dietary intake and output, because the intake and output measurements may not be accurate. In the case of fluid retention resulting from congestive heart failure, diuretics may be required.

In megaloblastic forms of anemia, the significant potential complications are neurologic. A neurologic assessment should be performed for patients with known or suspected megaloblastic anemia. Patients may initially complain of paresthesias in their lower extremities. These paresthesias are usually manifested as numbness and tingling on the bottom of the foot, and they gradually progress. As the anemia progresses and damage to the spinal cord occurs, other signs become apparent. Position and vibration sense may be diminished; difficulty maintaining balance is not uncommon, and some patients have gait disturbances as well. Initially mild but gradually progressive confusion may develop.

Evaluation

EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Tolerates activity at a safe and acceptable level
   a. Follows a progressive plan of rest, activity, and exercise
   b. Prioritizes activities
   c. Paces activities according to energy level
2. Attains and maintains adequate nutrition
   a. Eats a healthy diet
   b. Develops meal plan that promotes optimal nutrition
   c. Maintains adequate amounts of iron, vitamins, and protein from diet or supplements
   d. Adheres to nutritional supplement therapy when prescribed
   e. Verbalizes understanding of rationale for using recommended nutritional supplements
   f. Verbalizes understanding of rationale for avoiding non-recommended nutritional supplements

3. Maintains adequate perfusion
   a. Has vital signs within baseline for patient
   b. Has pulse oximetry (arterial oxygenation) value within normal limits
4. Absence of complications
   a. Avoids or limits activities that cause dyspnea, palpitations, dizziness, or tachycardia
   b. Uses rest and comfort measures to alleviate dyspnea
   c. Has vital signs within baseline for patient
   d. Has no signs of increasing fluid retention (eg, peripheral edema, decreased urine output, neck vein distention)
e. Remains oriented to time, place, and situation
f. Ambulates safely, using assistive devices as necessary
g. Remains free of injury
h. Verbalizes understanding of importance of serial CBC measurements
i. Maintains safe home environment; obtains assistance as necessary.

Hypoproliferative Anemias

IRON DEFICIENCY ANEMIA

Iron deficiency anemia typically results when the intake of dietary iron is inadequate for hemoglobin synthesis. The body can store about one fourth to one third of its iron, and it is not until those stores are depleted that iron deficiency anemia actually begins to develop. Iron deficiency anemia is the most common type of anemia in all age groups, and it is the most common anemia in the world. More than 500 million people are affected, more commonly in underdeveloped countries, where inadequate iron stores can result from inadequate intake of iron (seen with vegetarian diets) or from blood loss (eg, from intestinal hookworm). Iron deficiency is also common in the United States. In children, adolescents, and pregnant women, the cause is typically inadequate iron in the diet to keep up with increased growth. However, for most adults with iron deficiency anemia, the cause is blood loss. In fact, in adults, the cause of iron deficiency anemia should be considered to be bleeding until proven otherwise.

The most common cause of iron deficiency in men and postmenopausal women is bleeding (from ulcers, gastritis, inflammatory bowel disease, or gastrointestinal tumors). The most common cause of iron deficiency anemia in premenopausal women is menorrhagia (excessive menstrual bleeding) and pregnancy with inadequate iron supplementation. Patients with chronic alcoholism often have chronic blood loss from the gastrointestinal tract, which causes iron loss and eventual anemia. Other causes include iron malabsorption, as is seen after gastrectomy or with celiac disease.

Clinical Manifestations

Patients with iron deficiency primarily have the symptoms of anemia. If the deficiency is severe or prolonged, they may also have a smooth, sore tongue, brittle and ridged nails, and angular cheilosis (an ulceration of the corner of the mouth). These signs subside after iron-replacement therapy. The health history may be significant for unusual substances, such as ice, clay, or laundry starch.

Assessment and Diagnostic Findings

The most definitive method of establishing the diagnosis of iron deficiency anemia is bone marrow aspiration. The aspirate is stained to detect iron, which is at a low level or even absent. However, few patients with suspected iron deficiency anemia undergo bone marrow aspiration. In many patients, the diagnosis can be established with other tests, particularly in patients with a history of conditions that predispose them to this type of anemia.

There is a strong correlation between laboratory values measuring iron stores and levels of hemoglobin. After the iron stores are depleted (as reflected by low serum ferritin levels), the hemoglobin level falls. The diminished iron stores cause small RBCs. Therefore, as the anemia progresses, the MCV, which measures the size of the RBC, also decreases. Hematocrit and RBC levels are also low in relation to the hemoglobin level. Other laboratory tests that measure iron stores are useful but are not as consistent indicators as a low ferritin level, which reflects low iron stores. Typically, patients with iron deficiency anemia have a low serum iron level and an elevated TIBC, which measures the transport protein supplying the marrow with iron as needed (also referred to as transferrin). However, other disease states, such as infection and inflammatory conditions, can also cause a low serum iron level and TIBC with an elevated ferritin level. Therefore, the most reliable laboratory findings in evaluating iron deficiency anemia are the ferritin and hemoglobin values.

Medical Management

Except in the case of pregnancy, the cause of iron deficiency should be investigated. Anemia may be a sign of a curable gastrointestinal cancer or of uterine fibroid tumors. Stool specimens should be tested for occult blood. People 50 years of age or older should have a colonoscopy, endoscopy, or other examination of the gastrointestinal tract to detect ulcerations, gastritis, polyps, or cancer. Several oral iron preparations—ferrous sulfate, ferrous gluconate, and ferrous fumarate—are available for treating iron deficiency anemia. In some cases, oral iron is poorly absorbed or poorly tolerated, or iron supplementation is needed in large amounts. In these situations, intravenous or intramuscular administration of iron dextran may be needed. Before parenteral administration of a full dose, a small test dose should be administered to avoid the risk of anaphylaxis with either intravenous or intramuscular injections. Emergency medications (eg, epinephrine) should be at the bedside. If no signs of allergic reaction have occurred after 30 minutes, the remaining dose of iron may be administered. Several doses are required to replenish the patient’s iron stores.

Nursing Management

Preventive education is important, because iron deficiency anemia is common in menstruating and pregnant women. Food sources high in iron include organ meats (beef or calf’s liver, chicken liver), other meats, beans (black, pinto, and garbanzo), leafy green vegetables, raisins, and molasses. Taking iron-rich foods with a source of vitamin C enhances the absorption of iron.

The nurse helps the patient select a healthy diet. Nutritional counseling can be provided for those whose usual diet is inadequate. Patients with a history of eating fad diets or strict vegetarian diets are counseled that such diets often contain inadequate amounts of absorbable iron. The nurse encourages patients to continue iron therapy as long as it is prescribed, although they may no longer feel fatigued.

Because iron is best absorbed on an empty stomach, patients should be advised to take the supplement an hour before meals. Most patients can use the less expensive, more standard forms of ferrous sulfate. Tablets with enteric coating may be poorly
ANEMIAS IN RENAL DISEASE

The degree of anemia in patients with end-stage renal disease varies greatly, but in general patients do not become significantly anemic until the serum creatinine level exceeds 3 mg/100 mL. The symptoms of anemia are often the most disturbing of the patient’s symptoms. The hematocrit usually falls to between 20% and 30%, although in rare cases it may fall to less than 15%. The RBCs appear normal on the peripheral smear.

This anemia is caused by both a mild shortening of RBC life span and a deficiency of erythropoietin (necessary for erythropoiesis). As renal function decreases, erythropoietin, which is produced by the kidney, also decreases. Because erythropoietin is also produced outside the kidney, some erythropoiesis does continue, even in patients whose kidneys have been removed. However, the amount is small and the degree of erythropoiesis is inadequate.

Patients undergoing long-term hemodialysis lose blood into the dialyzer and therefore may become iron deficient. Folic acid deficiency develops because this vitamin passes into the dialysate. Therefore, patients who receive hemodialysis and who are anemic should be evaluated for iron and folate deficiency and treated appropriately.

The availability of recombinant erythropoietin (epoetin alfa [Epogen, Procrit]) has dramatically altered the management of anemia in end-stage renal disease by decreasing the need for RBC transfusion, with its associated risks. Erythropoietin, in combination with oral iron supplements, can raise and maintain hematocrit levels to between 33% and 38%. This treatment has been successful with dialysis patients. Many patients report decreased fatigue, increased energy, increased feelings of well-being, improved exercise tolerance, better tolerance of dialysis treatments, and improved quality of life. Hypertension is the most serious side effect in this patient population when the hematocrit rapidly increases to a high level. Therefore, the hematocrit should be checked frequently when a patient with renal disease begins erythropoietin therapy. The dose of erythropoietin (epoetin alfa) should be titrated to the hematocrit. In some patients, the elevated hematocrit and associated hypertension may necessitate antihypertensive therapy.

ANEMIA OF CHRONIC DISEASE

The term “anemia of chronic disease” is a misnomer in that only the chronic diseases of inflammation, infection, and malignancy cause this type of anemia. Many chronic inflammatory diseases are associated with a normochromic, normocytic anemia (ie, the RBCs are normal in color and size). These disorders include rheumatoid arthritis; severe, chronic infections; and many cancers. It is therefore imperative that the “chronic disease” be diagnosed when this form of anemia is identified so that it can be appropriately managed.

The anemia is usually mild to moderate and nonprogressive. It develops gradually over 6 to 8 weeks and then stabilizes at a hematocrit seldom less than 25%. The hemoglobin level rarely falls below 9 g/dL, and the bone marrow has normal cellularity.

Iron supplementation is usually given in oral form, typically as ferrous sulfate, or FeSO₄. Many patients have difficulty tolerating iron supplements, primarily due to gastrointestinal toxicities (eg, nausea, abdominal discomfort, constipation). Here are some helpful guidelines for taking iron supplements:

- Take iron on an empty stomach (1 hour before or 2 hours after a meal). Iron absorption is reduced with food, especially dairy products.
- To prevent gastrointestinal distress, the following schedule may work better if more than one tablet a day is prescribed: Start with only one tablet per day for a few days, then increase to two tablets per day, then three tablets per day. This method permits the body to adjust gradually to the iron.
- Increase the intake of vitamin C (citrus fruits and juices, strawberries, tomatoes, broccoli), to enhance iron absorption.
- Eat foods high in fiber to minimize problems with constipation.
- Remember that stools will become dark in color. Poly saccharide iron complex forms are better tolerated but are more expensive. Liquid forms of iron supplementation may be better tolerated than solid forms, although they are more expensive. The liquid forms can discolor teeth. Use a straw or place the spoon at the back of the mouth to take the supplement; rinse mouth thoroughly afterward.
with increased stores of iron as the iron is diverted from the serum (and thus is unavailable as a growth factor for invading pathogens). Erythropoietin levels are low, perhaps because of decreased production, and iron use is blocked by erythroid cells (cells that are or will become mature RBCs). A moderate shortening of RBC survival also occurs.

Most of these patients have few symptoms and do not require treatment for the anemia. With successful treatment of the underlying disorder, the bone marrow iron is used to make RBCs and the hemoglobin level rises.

APLASTIC ANEMIA

Aplastic anemia is a rather rare disease caused by a decrease in or damage to marrow stem cells, damage to the microenvironment within the marrow, and replacement of the marrow with fat. It results in bone marrow aplasia (markedly reduced hematopoiesis). Therefore, in addition to severe anemia, significant neutropenia and thrombocytopenia (a deficiency of platelets) are also seen.

Pathophysiology

Aplastic anemia can be congenital or acquired, but most cases are idiopathic (ie, without apparent cause). Infections and pregnancy can trigger it, or it may be caused by certain medications, chemicals, or radiation damage (Chart 33-3). Agents that regularly produce marrow aplasia include benzene and benzene derivatives (eg, airplane glue). Certain toxic materials, such as inorganic arsenic and several pesticides (including DDT, which is no longer used or available in the United States), have also been implicated as potential causes. Various medications have been associated with aplastic anemia.

Clinical Manifestations

The manifestations of aplastic anemia are often insidious. Complications resulting from bone marrow failure may occur before the diagnosis is established. Typical complications are infection and symptoms of anemia (eg, fatigue, pallor, dyspnea). Purpura (bruising) may develop later and should trigger a CBC and hematologic evaluation if these were not performed initially. If the patient has had repeated throat infections, cervical lymphadenopathy may be seen. Other lymphadenopathies and splenomegaly sometimes occur. Retinal hemorrhages are common.

Assessment and Diagnostic Findings

In many situations, aplastic anemia occurs when a medication or chemical is ingested in toxic amounts. However, in a few people, it develops after a medication has been taken at the recommended dosage. This may be considered an idiosyncratic reaction in those who are highly susceptible, possibly caused by a genetic defect in the medication biotransformation or elimination process. A bone marrow aspirate shows an extremely hypoplastic or even aplastic (very few to no cells) marrow replaced with fat.

Medical Management

It is presumed that the lymphocytes of patients with aplastic anemia destroy the stem cells and consequently impair the production of RBCs, WBCs, and platelets. Despite its severity, aplastic anemia can be successfully treated in most people. Potentially, those who are younger than 60 years of age, who are otherwise healthy, and who have a compatible donor can be cured of the disease by a bone marrow transplantaton (BMT) or peripheral stem cell transplantation (BSCT). In others, the disease can be managed with immunosuppressive therapy. A combination of antithymocyte globulin and cyclosporine is used most commonly. Immunosuppressants prevent the patient’s lymphocytes from destroying the stem cells. If relapse occurs (ie, the patient becomes pancytopenic again), reinstitution of the same immunologic agents may induce another remission. Corticosteroids are not very useful as an immunosuppressive agent, because patients with aplastic anemia appear particularly susceptible to the development of bone complications from corticosteroids (ie, aseptic necrosis of the head of the femur).

Supportive therapy plays a major role in the management of aplastic anemia. Any offending agent is discontinued. The patient is supported with transfusions of RBCs and platelets as necessary. Death usually is caused by hemorrhage or infection.

Nursing Management

Patients with aplastic anemia are vulnerable to problems related to RBC, WBC, and platelet deficiencies. They should be assessed carefully for signs of infection and bleeding. Specific interventions are delineated in the sections on neutropenia and thrombocytopenia.

MEGALOBLASTIC ANEMIAS

In the anemias caused by deficiencies of vitamin B₁₂ or folic acid, identical bone marrow and peripheral blood changes occur, because both vitamins are essential for normal DNA synthesis. In either anemia, the RBCs that are produced are abnormally large and are called megaloblastic RBCs. Other cells derived from the myeloid stem cell (nonlymphoid WBCs, platelets) are also abnor-

---
A deficiency of vitamin B₁₂ can occur in several ways. Inadequate failure to secrete intrinsic factor. Therefore, the absorption of vitamin B₁₂ primarily a disorder of adults, particularly the elderly. The absorption may occur if disease involving the ileum or pancreas impairs absorption. Vitamin B₁₂ travels with it to the ileum, where the vitamin is absorbed. Without the intrinsic factor, orally consumed vitamin B₁₂ cannot be absorbed, and RBC production is eventually diminished. Even if adequate vitamin B₁₂ and intrinsic factor are present, a deficiency may occur if disease involving the ileum or pancreas impairs absorption. Pertussis anemia, which tends to run in families, is primarily a disorder of adults, particularly the elderly. The abnormality is in the gastric mucosa: the stomach wall atrophies and fails to secrete intrinsic factor. Therefore, the absorption of vitamin B₁₂ is significantly impaired.

The body normally has large stores of vitamin B₁₂, so years may pass before the deficiency results in anemia. Because the body compensates so well, the anemia can be severe before the patient becomes symptomatic. For unknown reasons, patients with pernicious anemia have a higher incidence of gastric cancer than the general population; these patients should have endoscopies at regular intervals (every 1 to 2 years) to screen for early gastric cancer.

Pathophysiology

FOLIC ACID DEFICIENCY

Folic acid, a vitamin that is necessary for normal RBC production, is stored as compounds referred to as folates. The folate stores in the body are much smaller than those of vitamin B₁₂, and they are quickly depleted when the dietary intake of folate is deficient (within 4 months). Folate is found in green vegetables and liver. Folate deficiency occurs in people who rarely eat uncooked vegetables. Alcohol increases folic acid requirements, and, at the same time, patients with alcoholism usually have a diet that is deficient in the vitamin. Folic acid requirements are also increased in patients with chronic hemolytic anemias and in women who are pregnant, because the need for RBC production is increased in these conditions. Some patients with malabsorptive diseases of the small bowel, such as sprue, may not absorb folic acid normally.

VITAMIN B₁₂ DEFICIENCY

A deficiency of vitamin B₁₂ can occur in several ways. Inadequate dietary intake is rare but can develop in strict vegetarians who consume no meat or dairy products. Faulty absorption from the gastrointestinal tract is more common. This occurs in conditions such as Crohn’s disease, or after ileal resection or gastrectomy. Another cause is the absence of intrinsic factor, as in pernicious anemia. Intrinsic factor is normally secreted by cells within the gastric mucosa; normally it binds with the dietary vitamin B₁₂ and travels with it to the ileum, where the vitamin is absorbed. Without intrinsic factor, orally consumed vitamin B₁₂ cannot be absorbed, and RBC production is eventually diminished. Even if adequate vitamin B₁₂ and intrinsic factor are present, a deficiency may occur if disease involving the ileum or pancreas impairs absorption. Pernicious anemia, which tends to run in families, is primarily a disorder of adults, particularly the elderly. The abnormality is in the gastric mucosa: the stomach wall atrophies and fails to secrete intrinsic factor. Therefore, the absorption of vitamin B₁₂ is significantly impaired.

The body normally has large stores of vitamin B₁₂, so years may pass before the deficiency results in anemia. Because the body compensates so well, the anemia can be severe before the patient becomes symptomatic. For unknown reasons, patients with pernicious anemia have a higher incidence of gastric cancer than the general population; these patients should have endoscopies at regular intervals (every 1 to 2 years) to screen for early gastric cancer.

Clinical Manifestations

Symptoms of folic acid and vitamin B₁₂ deficiencies are similar, and the two anemias may coexist. However, the neurologic manifestations of vitamin B₁₂ deficiency do not occur with folic acid deficiency, and they persist if B₁₂ is not replaced. Therefore, careful distinction between the two anemias must be made. Serum levels of both vitamins can be measured. In the case of folic acid deficiency, even small amounts of folate will increase the serum folate level, sometimes to normal. Measuring the amount of folate within the RBC itself (red cell folate) is therefore a more sensitive test in determining true folate deficiency.

After the body stores of vitamin B₁₂ are depleted, patients may begin to show signs of the anemia. However, because the onset and progression of the anemia are so gradual, the body can compensate very well until the anemia is severe, so that the typical manifestations of anemia (weakness, listlessness, fatigue) may not be apparent initially. The hemolytic effects of deficiency are accompanied by effects on other organ systems, particularly the gastrointestinal tract and nervous system. Patients with pernicious anemia develop a smooth, sore, red tongue and mild diarrhea. They are extremely pale, particularly in the mucous membranes. They may become confused; more often they have paresthesias in the extremities (particularly numbness and tingling in the feet and lower legs). They may have difficulty maintaining their balance because of damage to the spinal cord, and they also lose position sense (proprioception). These symptoms are progressive, although the course of illness may be marked by spontaneous partial remissions and exacerbations. Without treatment, patients can die after several years, usually from heart failure secondary to anemia.

Assessment and Diagnostic Findings

The classic method of determining the cause of vitamin B₁₂ deficiency is the Schilling test, in which the patient receives a small oral dose of radioactive vitamin B₁₂, followed in a few hours by a large, nonradioactive parenteral dose of vitamin B₁₂ (this aids in renal excretion of the radioactive dose). If the oral vitamin is absorbed, more than 8% will be excreted in the urine within 24 hours; therefore, if no radioactivity is present in the urine (ie, the radioactive vitamin B₁₂ stays within the gastrointestinal tract), the cause is gastrointestinal malabsorption of the vitamin B₁₂. Conversely, if the urine is radioactive, the cause of the deficiency is not ileal disease or pernicious anemia. Later, the same procedure is repeated, but this time intrinsic factor is added to the oral radioactive vitamin B₁₂. If radioactivity is now detected in the urine (ie, the B₁₂ was absorbed from the gastrointestinal tract in the presence of intrinsic factor), the diagnosis of pernicious anemia can be made. The Schilling test is useful only if the urine collections are complete; therefore, the nurse must promote the patient’s understanding and ability to comply with this collection.

Another useful, easier test is the intrinsic factor antibody test. A positive test indicates the presence of antibodies that bind the vitamin B₁₂-intrinsic factor complex and prevent it from binding to receptors in the ileum, thus preventing its absorption. Unfortunately, this test is not specific for pernicious anemia alone, but it can aid in the diagnosis.

Medical Management

Folate deficiency is treated by increasing the amount of folic acid in the diet and administering 1 mg of folic acid daily. Folic acid is administered intramuscularly only for people with malab-
MELODYPOSPLASTIC SYNDROMES (MDS)

The MDSs are a group of disorders of the myeloid stem cell that cause dysplasia (abnormal development) in one or more types of cell lines. The most common feature of MDS—dysplasia of the RBCs—is manifested as a macrocytic anemia; however, the WBCs (myeloid cells, particularly neutrophils) and platelets can also be affected. Although the bone marrow is actually hypercellular, many of the cells within it die before being released into the circulation. Therefore, the number of affected cells in the circulation is typically lower than normal. In addition to the quantitative defect (ie, fewer cells than normal), there is also a qualitative defect: the cells are not as functional as normal. The neutrophils have diminished ability to destroy bacteria by phagocytosis; platelets are less able to aggregate and are less adhesive than usual. The result of these qualitative defects is an increased risk for infection and bleeding, even when the actual number of circulating cells may not be excessively low. A significant proportion of MDS cases evolve into acute myeloid leukemia (AML); this type of leukemia tends to be nonresponsive to standard therapy.

Primary MDS tends to be a disease of the elderly; more than 80% of patients with MDS are older than 60 years of age. Secondary MDS may occur at any age and results from prior toxic exposure to chemicals, including chemotherapeutic medications (particularly alkylating agents). Secondary MDS tends to have a poorer prognosis than does primary MDS.

Clinical Manifestations

The manifestations of MDS can vary widely. Many patients are asymptomatic, with the illness being discovered incidentally when a CBC is performed for other purposes. Other patients have profound symptoms and complications from the illness. Fatigue is often present, at varying levels. Neutrophil dysfunction renders the person at risk for infection; recurrent pneumonias are not uncommon. Because platelet function can also be altered, bleeding can occur. These problems may persist in a fairly steady state for months, even years. They may also progress over time; as the dysplasia evolves into a leukemic state, the complications increase in severity.

Assessment and Diagnostic Findings

The CBC typically reveals a macrocytic anemia; WBC and platelet counts may be diminished as well. Serum erythropoietin levels may be inappropriately low, as is the reticulocyte count. As the disease evolves into AML, more immature blast cells are noted on the CBC.

Medical Management

With the exception of allogeneic bone marrow transplantation (BMT), there is no known cure for MDS. Chemotherapy has been used, particularly in patients with more aggressive forms of the illness, typically with disappointing results (Deeg & Applebaum, 2000; Beran, 2000). However, patients with mild cytopenias (low blood counts) actually require no therapy. For most patients with MDS, transfusions of RBCs are required to control the anemia and its symptoms. These patients can develop significant problems with iron overload from the repeated transfusions; this problem can be diminished with prompt initiation of chelation therapy to remove the excess iron (see Nursing Management). In some patients, the use of erythropoietin can be successful in
The erythropoietin stimulates the bone marrow to compensate by stimulating an increase in erythropoietin release from the kidney. In decreased oxygen availability causes hypoxia, which in turn reduces the number of RBCs in circulation. Fewer RBCs result in hemolytic anemias, where the RBCs have a shortened life span; thus, patients may require ongoing platelet transfusions to prevent significant bleeding. Infections need to be managed aggressively and promptly. Administration of growth factors, particularly granulocyte colony-stimulating factor (G-CSF), erythropoietin, or both, has been successful in increasing neutrophils and diminishing anemia in certain patients; however, these agents are expensive and the effect is lost if the medications are stopped.

Nursing Management

Caring for patients with MDS can be challenging because the illness is unpredictable. As with other hematologic conditions, some patients (especially those with no symptoms) have difficulty perceiving that they have a serious illness that can place them at risk for life-threatening complications. At the other extreme, many patients have tremendous difficulty coping with the uncertain trajectory of the illness and fear that the illness will evolve into AML at a time when they are feeling very well physically.

Patients with MDS need extensive instruction about infection risk, measures to avoid it, signs and symptoms of developing infection, and appropriate actions to initiate should such symptoms occur. Instruction should also be given regarding the risk for bleeding. Patients with MDS who are hospitalized may require neutropenic precautions.

Laboratory values need to be monitored closely to anticipate the need for transfusion and to determine how response to treatment with growth factors. Patients with chronic transfusion requirements usually benefit from a vascular access device for this purpose. Patients receiving growth factors or chelation therapy must be educated about these medications, their side effects, and administration techniques.

Chelation therapy is a process that is used to remove excess iron acquired from chronic transfusions. Iron is bound to a substance, the chelating agent, and then excreted in the urine. Oral forms of chelating agents have not been successful (due to either diminished efficacy or excessive toxicity). Chelation therapy is most effective as a subcutaneous infusion administered over 8 to 12 hours; most patients prefer to do this at night. Because chelation therapy removes only a small amount of iron with each treatment, patients with chronic transfusion requirements (and iron overload) need to continue chelation therapy as long as the iron overload exists, potentially for the rest of their lives. Patients who are embarking on chelation therapy must be highly motivated and need instruction in the subcutaneous infusion technique, infusion pump maintenance, and side effect management. Local erythema at the injection site is the most common reaction and typically requires no intervention. Patients should have baseline and annual auditory and eye examinations, because hearing loss and visual changes can occur with treatment.

Hemolytic Anemias

In hemolytic anemias, the RBCs have a shortened life span; thus, the number of RBCs in circulation is reduced. Fewer RBCs result in decreased in available oxygen causes hypoxia, which in turn stimulates an increase in erythropoietin release from the kidney. The erythropoietin stimulates the bone marrow to compensate by producing new RBCs and releasing some of them into the circulation somewhat prematurely as reticulocytes. If the RBC destruction persists, the hemoglobin is broken down excessively; about 80% of the heme is converted to bilirubin, conjugated in the liver, and excreted in the bile.

The mechanism of RBC destruction varies, but all types of hemolytic anemia share certain laboratory features: the reticulocyte count is elevated, the fraction of indirect (unconjugated) bilirubin is increased, and the supply of haptoglobin (a binding protein for free hemoglobin) is depleted as more hemoglobin is released. As a result, the plasma haptoglobin level is low. If the marrow cannot compensate to replace the RBCs (indicated by a decreased reticulocyte count), the anemia will progress.

Hemolytic anemia has various forms. Among the inherited forms are sickle cell anemia, thalassemia and thalassemia major, G-6-PD deficiency, and hereditary spherocytosis. Acquired forms include autoimmune hemolytic anemia, nonimmune-mediated paroxysmal nocturnal hemoglobinuria, microangiopathic hemolytic anemia, and heart valve hemolysis, as well as anemias associated with hypersplenism.

SICKLE CELL ANEMIA

Sickle cell anemia is a severe hemolytic anemia that results from inheritance of the sickle hemoglobin gene. This gene causes the hemoglobin molecule to be defective. The sickle hemoglobin (HbS) acquires a crystal-like formation when exposed to low oxygen tension. The oxygen level in venous blood can be low enough to cause this change; consequently, the RBC containing (HbS) loses its round, very pliable, biconcave disk shape and becomes deformed, rigid, and sickle-shaped (Fig. 33-5). These long, rigid RBCs can adhere to the endothelium of small vessels; when they pile up against each other, blood flow to a region or an organ may be reduced (Hoffman, et al., 2000). If ischemia or infarction results, the patient may have pain, swelling, and fever. The sickling process takes time; if the RBC is again exposed to adequate amounts of oxygen (eg, when it travels through the pulmonary circulation) before the membrane becomes too rigid, it can revert to a normal shape. For this reason, the “sickling crises” are intermittent. Cold can aggravate

FIGURE 33-5 A normal red blood cell (upper left) and a sickled red blood cell.
the sickling process, because vasoconstriction slows the blood flow. Oxygen delivery can also be impaired by an increased blood viscosity, with or without occlusion due to adhesion of sickled cells; in this situation, the effects are seen in larger vessels, such as arterioles.

The HbS gene is inherited in people of African descent and to a lesser extent in people from the Middle East, the Mediterranean area, and aboriginal tribes in India. Sickle cell anemia is the most severe form of sickle cell disease. Less severe forms include sickle cell hemoglobin C (SC) disease, sickle cell hemoglobin D (SD) disease, and sickle cell beta-thalassemia. The clinical manifestations and management are the same as for sickle cell anemia. The term sickle cell trait refers to the carrier state for SC diseases; it is the most benign type of SC disease, in that less than 50% of the hemoglobin within an RBC is HbS. However, in terms of genetic counseling, it is still an important finding. Two people with sickle cell trait have children, the children may inherit two abnormal genes. These children will produce only HbS and therefore will have sickle cell anemia.

**Clinical Manifestations**

Symptoms of sickle cell anemia vary and are only somewhat based on the amount of HbS. Symptoms and complications result from chronic hemolysis or thrombosis. The sickled RBCs have a shortened life span. Patients are always anemic, usually with hemoglobin values of 7 to 10 g/dL. Jaundice is characteristic and is usually obvious in the sclerae. The bone marrow expands in childhood in a compensatory effort to offset the anemia, sometimes leading to enlargement of the bones of the face and skull. The chronic anemia is associated with tachycardia, cardiac murmurs, and often an enlarged heart (cardiomegaly). Dysrhythmias and heart failure may occur in adults.

Virtually any organ may be affected by thrombosis, but the primary sites involve those areas with slowed circulation, such as the spleen, lungs, and central nervous system. All the tissues and organs are constantly vulnerable to microcirculatory interruptions by the sickling process and therefore are susceptible to hypoxic damage or true ischemic necrosis. Patients with sickle cell anemia are unusually susceptible to infection, particularly pneumonia and osteomyelitis. Complications of sickle cell anemia include infection, stroke, renal failure, impotence, heart failure, and pulmonary hypertension. Table 33-4 summarizes the complications resulting from sickle cell anemia.

**SICKLE CELL CRISIS**

There are three types of sickle cell crisis in the adult population. The most common is the very painful sickle crisis, which results from tissue hypoxia and necrosis due to inadequate blood flow to a specific region of tissue or organ. Aplastic crisis results from infection with the human parvovirus. The hemoglobin level falls rapidly and the marrow cannot compensate, as evidenced by an absence of reticulocytes. Sequestration crisis results when other organs pool the sickled cells. Although the spleen is the most common organ responsible for sequestration in children, by 10 years of age most children with sickle cell anemia have had a splenic infarction and the spleen is then no longer functional (autosplenectomy). In adults, the common organs involved in sequestration are the liver and, more seriously, the lungs.

**ACUTE CHEST SYNDROME**

Acute chest syndrome is manifested by a rapidly falling hemoglobin level, tachycardia, fever, and bilateral infiltrates seen on the chest x-ray. These signs often mimic infection; in fact, recent studies have identified infection as a major cause of acute chest syndrome (Vichinsky, et al., 2000). Another common cause is pulmonary fat embolism. Increased secretory phospholipase A₂

*Problems encountered in sickle cell anemia vary and are the result of a variety of mechanisms, as depicted in this table. Common physical findings and symptoms are also variable.

†sPLA₂: Secretory phospholipase A₂, a laboratory test that can predict impending acute chest syndrome (see text).
concentration has been identified as a predictor of impending acute chest syndrome; the increased amounts of free fatty acids can cause increased permeability of the pulmonary endothelium and leakage of the pulmonary capillaries. Although this syndrome is potentially lethal, prompt intervention can result in a favorable outcome.

**Assessment and Diagnostic Findings**

The patient with sickle cell trait usually has a normal hemoglobin level, a normal hematocrit, and a normal blood smear. In contrast, the patient with sickle cell anemia has a low hematocrit and sickled cells on the smear. The diagnosis is confirmed by hemoglobin electrophoresis.

**Prognosis**

Patients with sickle cell anemia are usually diagnosed in childhood, because they become anemic in infancy and begin to have sickle cell crises at 1 or 2 years of age. Some children die in the first years of life, typically from infection, but the use of antibiotics and parent teaching have greatly improved the outcomes for these children. However, with current management strategies, the average life expectancy is still suboptimal, at 42 years. Young adults are often forced to live with multiple, often severe, complications from their disease. In some patients, the symptoms and complications diminish by 30 years of age; these patients live into the sixth decade or longer. At this time, there is no way to predict which patients will fall into this subgroup.

**Medical Management**

Treatment for sickle cell anemia is the focus of continued research (Steinberg, 1999). Many trials of medications that have antiscickling properties are being conducted, as is research using antiadhesion treatment for vasoocclusive crises. However, aside from the equally important aggressive management of symptoms and complications, currently there are only three primary treatment modalities for sickle cell diseases: BMT, hydroxyurea, and long-term RBC transfusion.

BMT offers the potential for cure for this disease. However, this treatment modality is available to only a small subset of the patient population, because of either the lack of a compatible donor or the severe organ (eg, renal, liver, lung) damage already present in the patient.

**PHARMACOLOGIC THERAPY**

Hydroxyurea (Hydrea), a chemotherapy agent, has been shown to be effective in increasing hemoglobin F levels in patients with sickle cell anemia, thereby decreasing the permanent formation of sickled cells. Patients who receive hydroxyurea appear to have fewer painful episodes of sickle cell crisis, a lower incidence of acute chest syndrome, and less need for transfusions (Ferster et al., 2001). However, whether hydroxyurea can prevent or reverse actual organ damage remains unknown. Side effects of hydroxyurea include chronic suppression of WBC formation, teratogenesis, and potential for later development of a malignancy. Patient response to the medication varies significantly. The incidence and severity of side effects are also highly variable within a dose range. Some patients have toxicity when receiving a very small dose (5 mg/kg per day), whereas others have little toxicity with a much higher dose (35 mg/kg per day). More research is needed to identify specific patient subgroups that are more likely to respond to this medication.

**TRANSFUSION THERAPY**

Chronic transfusions with RBCs have been shown to be highly effective in several situations: in an acute exacerbation of anemia (eg, aplastic crisis), in the prevention of severe complications from anesthesia and surgery, and in improving the response to infection (when it results in exacerbated anemia) (Ohene-Frempong, 2001). Chronic transfusions have also been shown to be effective in diminishing episodes of sickle cell crisis in pregnant women; however, these transfusions have not been shown to improve fetal survival. Transfusion therapy may be effective in preventing complications from sickle cell disease. Although controversial, some data support the use of chronic transfusions in patients with cerebral ischemic injury (as seen on magnetic resonance imaging [MRI] or Doppler studies) to prevent more severe injury (eg, CVA). More than 50% of asymptomatic patients have some cerebral ischemia documented by MRI. In a recent study (Adams, 2000), chronic transfusion with RBCs resulted in a 90% reduction of stroke in children at risk for this complication, as demonstrated by elevated blood viscosity on transcranial Doppler ultrasonography. Transfusions may also be useful in the management of severe cases of acute chest syndrome.

The risk of complications from transfusion is important to consider. These risks include iron overload, which necessitates chronic chelation therapy (see MDS Nursing Management); poor venous access, which necessitates a vascular access device (and its attendant risk for infection or thrombosis); infections (hepatitis, human immunodeficiency virus [HIV]); and alloimmunization from repeated transfusions. Another complication from transfusion is the increased viscosity of blood before the concentration of hemoglobin S is reduced. Exchange transfusion (in which the patient’s own blood is removed and replaced via transfusion) may be performed to diminish the risk of increasing the viscosity excessively; the objective is to reduce the hematocrit to less than 30%, with transfusions supplying more than 80% of the patient’s blood volume. Finally, it is important to consider the significant financial cost of an aggressive transfusion and chelation program.

Patients with sickle cell anemia require daily folic acid replacements to maintain the supply required for increased erythropoiesis from hemolysis. Infections must be treated promptly with appropriate antibiotics; infection remains a major cause of death in these patients.

Acute chest syndrome is managed by prompt initiation of antibiotic therapy. Incentive spirometry has been shown to decrease the incidence of pulmonary complications significantly. In severe cases, bronchoscopy may be required to identify the source of pulmonary disease. Fluid restriction may be more beneficial than aggressive hydration. Corticosteroids may also be useful. Transfusions reverse the hypoxia and decrease the level of secretory phospholipase A₂. Pulmonary function should be monitored regularly to detect pulmonary hypertension early, when therapy (hydroxyurea, transfusions, or transplantation) may have a positive impact.

Because repeated blood transfusions are necessary, patients may develop multiple autoantibodies, making cross-matching difficult. In this patient population, a hemolytic transfusion reaction (see later discussion) may mimic the signs and symptoms of a sickle cell crisis. The classic distinguishing factor is that, with a hemolytic transfusion reaction, the patient becomes more anemic after being transfused. These patients need very close observation. Further transfusion is avoided if possible until the hemolytic process abates. If possible, the patient is supported with corticosteroids (Prednisone), intravenous immunoglobulin (IVIG; Gammagard, Sandoglobulin, Venoglobulin), and erythropoietin (Epogen, Procrit).
**SUPPORTIVE THERAPY**

Supportive care is equally important. A significant issue is pain management. The incidence of painful sickle cell crises is highly variable; many patients have pain on a daily basis. The severity of the pain may not be enough to cause the patient to seek assistance from health care providers but severe enough to interfere with the ability to work and function within the family. Acute pain episodes tend to be self-limited, lasting hours to days. If the patient cannot manage the pain at home, intervention is frequently sought in the acute care setting, usually at an urgent care facility or emergency department. Adequate hydration is important during a painful sickling episode. Oral hydration is acceptable if the patient can maintain adequate amounts of fluids; intravenous hydration with dextrose 5% in water (D5W) or dextrose 5% in 0.25 normal saline solution (3 L/m²/24 hours) is usually required for sickle crisis. Supplemental oxygen may also be needed.

The use of medication to relieve pain is important (see Chap. 13 for a discussion of pain management). Aspirin is very useful in diminishing mild to moderate pain; it also diminishes inflammation and potential thrombosis (due to its ability to diminish platelet adhesion). Nonsteroidal anti-inflammatory drugs (NSAIDs) are useful for moderate pain or in combination with opioid analgesics. Although no tolerance develops with NSAIDs, a “ceiling effect” does develop whereby an increase in dosage does not increase analgesia. NSAID use must be carefully monitored, because these medications can precipitate renal dysfunction. When opioid analgesics are used, morphine is the medication of choice for acute pain. Patient-controlled analgesia is frequently used.

Chronic pain increases in incidence as the patient ages. Here, the pain is caused by complications from the sickling, such as avascular necrosis of the hip. With chronic pain management, the principal goal is to maximize functioning; pain may not be completely eliminated without sacrificing function. This concept may be difficult for patients to accept; they may need repeated explanations and support from nonjudgmental health care providers. Nonpharmacologic approaches to pain management are crucial in this setting. Examples include physical and occupational therapy, physiotherapy (including the use of heat, massage, and exercise), cognitive and behavioral intervention (including distraction, relaxation, and motivational therapy), and support groups.

Working with patients who have multiple episodes of severe pain can be challenging. It is important for health care providers to realize that patients with sickle cell disease must face a lifelong experience with severe and unpredictable pain. Such pain is disruptive to the person’s level of functioning, including social functioning, and may result in a feeling of helplessness. Patients with inadequate social support systems may have more difficulty coping with chronic pain.

**NURSING PROCESS: THE PATIENT WITH SICKLE CELL CRISIS**

Patients in sickle cell crisis should be assessed for factors that could have precipitated the crisis, such as symptoms of infection or dehydration, or situations that promote fatigue or emotional stress.

**Assessment**

Patients are asked to recall factors that seemed to precipitate previous crises and measures they use to prevent and manage crises. Pain levels should always be monitored; a pain-rating scale, such as a 0-to-10 scale, best accomplishes this. The quality of the pain (eg, sharp, dull, burning), the frequency of the pain (constant versus intermittent), and factors that aggravate or alleviate the pain temporarily are included in this assessment. If a sickle cell crisis is suspected, the nurse needs to determine whether the pain currently experienced is the same as or different than the pain typically encountered in crisis.

Because the sickling process can interrupt circulation in any tissue or organ, with resultant hypoxia and ischemia, a careful assessment of all body systems is necessary. Particular emphasis is placed on assessing for pain, swelling, and fever. All joint areas are carefully examined for pain and swelling. The abdomen is assessed for pain and tenderness because of the possibility of splenic infarction.

The respiratory system must be assessed carefully, including auscultation of breath sounds, measurement of oxygen saturation levels, and signs of cardiac failure, such as the presence and extent of dependent edema, an increased point of maximal impulse, and cardiomegaly (as seen on chest x-ray). The patient should be assessed for signs of dehydration by a history of fluid intake and careful examination of mucous membranes, skin turgor, urine output, and serum creatinine and blood urea nitrogen values.

A careful neurologic examination is important to elicit symptoms of cerebral hypoxia. However, ischemic findings on MRI or Doppler studies may significantly precede the findings on the physical examination. MRI and Doppler studies are used for early diagnosis and may be more beneficial to improve patient outcome, because therapy can be initiated more promptly.

Because patients with sickle cell anemia are so susceptible to infections, they are assessed for the presence of any infectious process. Particular attention is given to examination of the chest, long bones, and femoral head, because pneumonia and osteomyelitis are especially common. Leg ulcers, which may be infected and are slow to heal, are common.

The extent of anemia (as measured by the hemoglobin level and the hematocrit) and the ability of the marrow to replenish RBCs (as measured by the reticulocyte count) should be monitored and compared with the patient’s baseline values. The patient’s current and past history of medical management should also be assessed, particularly chronic transfusion therapy, hydroxyurea use, and prior treatment for infection.

**Diagnosis**

**NURSING DIAGNOSES**

Based on the assessment data, major nursing diagnoses for the patient with sickle cell crisis may include:

- Acute pain related to tissue hypoxia due to agglutination of sickled cells within blood vessels
- Risk for infection
- Risk for powerlessness related to illness-induced helplessness
- Deficient knowledge regarding sickle crisis prevention

**COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS**

Based on the assessment data, potential complications may include:

- Hypoxia, ischemia, infection, and poor wound healing leading to skin breakdown and ulcers
- Dehydration
- Cerebrovascular accident (CVA, brain attack, stroke)
- Anemia
- Renal dysfunction
- Heart failure, pulmonary hypertension, and acute chest syndrome
- Impotence
- Poor compliance
- Substance abuse related to poorly managed chronic pain
Planning and Goals
The major goals for the patient are relief of pain, decreased incidence of crisis, enhanced sense of self-esteem and power, and absence of complications.

Nursing Interventions
MANAGING PAIN
Acute pain during a sickle cell crisis can be severe and unpredictable. The patient’s subjective description and rating of pain on a pain scale must guide the use of analgesics, which are valuable in controlling the acute pain of a sickle crisis. Any joint that is acutely swollen should be supported and elevated until the swelling diminishes. Relaxation techniques, breathing exercises, and distraction are helpful for some patients. After the acute painful episode has diminished, aggressive measures should be implemented to preserve function. Physical therapy, whirlpool baths, and transcutaneous nerve stimulation are examples of such modalities.

PREVENTING AND MANAGING INFECTION
Nursing care focuses on monitoring the patient for signs and symptoms of infection. Prescribed antibiotics should be initiated promptly, and the patient should be assessed for signs of dehydration. If the patient is to take prescribed oral antibiotics at home, he or she must understand the need to complete the entire course of antibiotic therapy and must be able to identify a feasible administration schedule.

PROMOTING COPING SKILLS
This illness, because of its acute exacerbations that often result in chronic health problems, frequently leaves the patient feeling powerless and with decreased self-esteem. These feelings can be exacerbated by inadequate pain management. The patient’s ability to use normal coping resources of physical strength, psychological stamina, and positive self-esteem is dramatically diminished. Enhancing pain management can be extremely useful in establishing a therapeutic relationship based on mutual trust. Nursing care that focuses on the patient’s strengths rather than deficits can enhance effective coping skills. Providing the patient with opportunities to make decisions about daily care may increase the patient’s feelings of control.

MINIMIZING DEFICIENT KNOWLEDGE
Patients with sickle cell anemia benefit from understanding what situations can precipitate a sickle cell crisis and the steps they can take to prevent or diminish such crises. Keeping warm and maintaining adequate hydration can be very effective in diminishing the occurrence and severity of attacks. Avoiding stressful situations is more challenging. Group education may be more effective if it is carried out by members of the community who are from the same ethnic group as those with the disease.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS
Management measures for many of the potential complications were delineated in previous sections. Other measures follow.

Leg Ulcers
Leg ulcers require careful management and protection from trauma and contamination. Referral to a wound care specialist may facilitate healing and assist with prevention. If leg ulcers fail to heal, skin grafting may be necessary. Scrupulous aseptic technique is warranted to prevent nosocomial infections.

Priapism Leading to Impotence
Male patients may develop sudden, painful episodes of priapism (persistent penile erection). The patient is taught to empty his bladder at the onset of the attack, exercise, and take a warm bath. If an episode persists longer than 3 hours, medical attention is recommended. Repeated episodes may lead to extensive vascular thrombosis, resulting in impotence.

Chronic Pain and Substance Abuse
Many patients have considerable difficulty coping with chronic pain and repeated episodes of sickle crisis. Those who feel they have little control over their health and the physical complications that result from this illness may find it difficult to understand the importance of complying with a prescribed treatment plan. Being nonjudgmental and actively seeking involvement from the patient in establishing a treatment plan are useful strategies.

Some patients with sickle cell anemia develop problems with substance abuse. For many, this abuse results from inadequate management of acute pain during episodes of crisis. Some clinicians suggest that abuse may result from prescribing inadequate amounts of opioid analgesics for an inadequate time. The patient’s pain may never be adequately relieved, promoting mistrust of the health care system and (from the patient’s perspective) the need to seek care from a variety of sources when the pain is not severe. This cycle is best managed by prevention. Receiving care from a single provider over time is much more beneficial than receiving care from rotating physicians and staff in an emergency department. When crises do arise, the staff in the emergency department should be in contact with the patient’s primary health care provider so that optimal management can be achieved. Once the pattern of substance abuse is established, it is very difficult to manage, but continuity of care and establishing written contracts with the patient can be useful management strategies.

PROMOTING HOME AND COMMUNITY-BASED CARE
Teaching Patients Self-Care
Because patients with sickle cell anemia are typically diagnosed as children, parents participate in the initial education. Based on the parents’ education, literacy, socioeconomic level, and interest, teaching focuses on the disease process (including some pathophysiology), treatment, and the assessment and monitoring skills for potential complications (see previous discussion). As the child ages, educational interventions with the child prepare the child to assume more responsibility for self-care.

Vascular access device management and chelation therapy can be taught to most families. Follow-up and care for patients with vascular access devices may also need to be provided by nurses in an outpatient facility or by a home care agency.

Continuing Care
The illness trajectory of sickle cell anemia is highly varied, with unpredictable episodes of complications and crises. Care is often provided on an emergency basis, especially for some patients with pain management problems (see previous section). Nurses in all settings used by this patient population need to communicate regularly with each other. Patients need to learn which parameters are important for them to monitor and how
to monitor them. Parameters should also be given as to when to seek urgent care.

**Evaluation**

**EXPECTED PATIENT OUTCOMES**

Expected patient outcomes may include:

1. Control of pain
   - Acute pain is controlled with analgesics
   - Uses relaxation techniques, breathing exercises, distraction to help relieve pain
2. Is free of infection
   - Has normal temperature
   - Shows WBC count within normal range (5000 to 10,000/mm³)
   - Identifies importance of continuing antibiotics at home (if applicable)
3. Expresses improved sense of control
   - Participates in goal setting and in planning and implementing daily activities
   - Participates in decisions about care
4. Increases knowledge about disease process
   - Identifies situations and factors that can precipitate sickle cell crisis
   - Describes lifestyle changes needed to prevent crisis
   - Describes the importance of warmth, adequate hydration, and prevention of infection in preventing crisis
5. Absence of complications

**THALASSEMIA**

The thalassemias are a group of hereditary disorders associated with defective hemoglobin-chain synthesis. These anemias occur worldwide, but the highest prevalence is found in people of Mediterranean, African, and Southeast Asian ancestry (Hoffman et al., 2000). Thalassemias are characterized by *hypochromia* (an abnormal decrease in the hemoglobin content of RBCs), extreme *microcytosis* (smaller-than-normal RBCs), destruction of blood elements (hemolysis), and variable degrees of anemia.

In thalassemia, the production of one or more globulin chains within the hemoglobin molecule is reduced. When this occurs, the imbalance in the configuration of the hemoglobin causes it to precipitate in the erythroid precursors or the RBCs themselves. This increases the rigidity of the RBCs and thus the premature destruction of these cells.

The thalassemias are classified into two major groups according to the globin chain diminished: alpha and beta. The alpha-thalassemias occur mainly in people from Asia and the Middle East; the beta-thalassemias are most prevalent in Mediterranean populations but also occur in people from the Middle East or Asia. The alpha-thalassemias are milder than the beta forms and often occur without symptoms. The RBCs are extremely microcytic, but the anemia, if present, is mild.

The severity of beta-thalassemia varies depending on the extent to which the hemoglobin chains are affected. Patients with mild forms have a microcytosis and mild anemia. If left untreated, severe beta-thalassemia (thalassemia major, or Cooley’s anemia) can be fatal within the first few years of life. If it is treated with regular transfusion of RBCs, patients may survive into their 20s and 30s. Patient teaching during the reproductive years should include pre-conception counseling about the risk of congenital thalassemia major.

**Thalassemia Major**

Thalassemia major (Cooley’s anemia) is characterized by severe anemia, marked hemolysis, and ineffective erythropoiesis (production of RBCs). With early regular transfusion therapy, growth and development through childhood are facilitated. Organ dysfunction due to iron overload results from the excessive amounts of iron obtained through the RBC transfusions. Regular chelation therapy (eg, via subcutaneous deferoxamine) has reduced the complications of iron overload and prolonged the life of these patients. This disease is potentially curable by BMT if the procedure can be performed before damage to the liver occurs (ie, during childhood).

**GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY**

The abnormality in this disorder is in the G-6-PD gene; this gene produces an enzyme within the RBC that is essential for membrane stability. A few patients have inherited an enzyme so defective that they have a chronic hemolytic anemia; however, the most common type of defect results in hemolysis only when the RBCs are stressed by certain situations, such as fever or the use of certain medications. The disorder came to the attention of researchers during World War II, when some soldiers developed hemolysis while taking primaquine, an antimalarial agent. African Americans and people of Greek or Italian origin are those primarily affected by this disorder. The type of deficiency found in the Mediterranean population is more severe than that in the African Caribbean population, resulting in greater hemolysis and sometimes in life-threatening anemia. All types of G-6-PD deficiency are inherited as X-linked defects; therefore, many more men are at risk than women. In the United States, about 12% of African American males are affected. The deficiency is also common in those of Asian ancestry and in certain Jewish populations.

Medications that have hemolytic effects for people with G-6-PD deficiency are oxidant drugs. These medications include antimalarial agents (eg, chloroquine [Aralen]), sulfonamides (eg, trimethoprim and sulfamethoxazole [Septra]), nitrofurantoin (eg, Macrobid or Macroantin), common coal tar analgesics (including aspirin in high doses), thiazide diuretics (eg, hydrochlorothiazide [HydroDIURIL], chlorothiazide [Diuril]), oral hypoglycemic agents (eg, glyburide [Micronase], metformin [Glucophage]), chloramphenicol (Chloromycetin), and vitamin K (phytonadione [Aqua-Mephyton]). In affected people, a severe hemolytic episode can result from ingestion of fava beans.

**Clinical Manifestations**

Patients are asymptomatic and have normal hemoglobin levels and reticulocyte counts most of the time. However, several days after exposure to an offending medication, they may develop pallor, jaundice, and hemoglobinuria (hemoglobin in the urine). The reticulocyte count rises, and symptoms of hemolysis develop. Special stains of the peripheral blood may then disclose Heinz bodies (degraded hemoglobin) within the RBCs. Hemolysis is often mild and self-limited. However, in the more severe Mediterranean type of G-6-PD deficiency, spontaneous recovery may not occur and transfusions may be necessary.

**Assessment and Diagnostic Findings**

The diagnosis is made by a screening test or by a quantitative assay of G-6-PD.
Medical Management

The treatment is to stop the offending medication. Transfusion is necessary only in the severe hemolytic state, which is more commonly seen in the Mediterranean variety of G-6-PD deficiency.

Nursing Management

The patient should be educated about the disease and given a list of medications to avoid. If hemolysis does develop, nursing interventions are the same as for hemolysis from other causes.

HEREDITARY SPHEROCYTOSIS

Here is a relatively common (1 in 5,000 people) hemolytic anemia characterized by an abnormal permeability of the RBC membrane; this permits the cells to change into a spherical shape. These RBCs are destroyed prematurely in the spleen. The severity of this hemolytic anemia varies; jaundice can be intermittent, and splenomegaly (enlarged spleen) also can occur. Surgical removal of the spleen is the principal treatment for this disorder.

IMMUNE HEMOLYTIC ANEMIA

Hemolytic anemias can result from exposure of the RBC to antibodies. Autoantibodies (ie, antibodies against the host, or "self") result from the immunization of an individual with foreign antigens (eg, the immunization of an Rh-negative person with Rh-positive blood). Autoantibodies tend to be large (IgM type) and cause immediate destruction of the sensitized RBCs, either within the blood vessel (intravascular hemolysis) or within the liver. The most common type of alloimmune hemolytic anemia in adults results from a hemolytic transfusion reaction.

Autoantibodies are developed by an individual for varying reasons. In many instances, the person's immune system is dysfunctional, so that it falsely recognizes its own RBCs as foreign and produces antibodies against them. This mechanism is seen in people with chronic lymphocytic leukemia (CLL). Another mechanism is a deficiency in suppressor lymphocytes, which normally prevent antibody formation against a person's own antigens. Autoantibodies tend to be of the IgG type. The RBCs are sequestered in the spleen and destroyed by the macrophages outside the blood vessel (extravascular hemolysis).

Autoimmune hemolytic anemias can be classified based on the body temperature involved when the antibodies react with the RBC antigen. Warm-body antibodies bind to RBCs most actively in warm conditions (37°C); cold-body antibodies react in cold (0°C). Most autoimmune hemolytic anemias are the warm-body type. Autoimmune hemolytic anemia is associated with other disorders in most cases (eg, medication exposure, lymphoma, CLL, other malignancy, collagen vascular disease, autoimmune disease, infection). In idiopathic autoimmune hemolytic states, the reason why the immune system produces the antibodies is not known. All ages and genders are equally vulnerable to this form, whereas the incidence of secondary forms is greater in people older than 45 years of age and in females.

Clinical Manifestations

Clinical manifestations can vary, and they usually reflect the degree of anemia. The hemolysis may be very mild, so that the patient's marrow compensates adequately and the patient is asymptomatic. At the other extreme, the hemolysis can be so severe that the resul-
should be emphasized. Similar teaching should be provided when immunosuppressive agents are used. Corticosteroid therapy is not without significant risk, and patients need to be monitored closely for complications. The short- and long-term complications of corticosteroid therapy are presented in Chart 33-4 and in Chap. 42.

**HEREDITARY HEMOCHROMATOSIS**

Hemochromatosis is a genetic condition in which iron is abnormally (excessively) absorbed from the gastrointestinal tract. The excessive iron is deposited in various organs, particularly the liver, myocardium, testes, thyroid, and pancreas. Eventually, the affected organs become dysfunctional. The actual incidence of hemochromatosis is unknown; however, hereditary hemochromatosis is diagnosed in 0.5% of the population in the United States (ie, 1 million people). Recent data suggest that this defect may be a common cause of diabetes (Schechter, et al., 2000). Because of their natural loss of iron through menses, women are less affected than men.

Because the accumulation of iron in body organs occurs gradually, there often is no evidence of tissue injury until middle age. Symptoms of weakness, lethargy, arthralgia, weight loss, and loss of libido are common. The skin may be hyperpigmented with melanin deposits (occasionally hemosiderin, an iron-containing pigment) and appears bronze in color. Cardiac dysrhythmias and cardiomyopathy can occur, with resulting dyspnea and edema. Endocrine dysfunction is manifested as hypothyroidism, diabetes mellitus, and hypogonadism (testicular atrophy, diminished libido, and impotence). A significant effect of hemochromatosis is the
development of hepatocellular carcinoma in one third of those affected. CBC values are typically normal. The most useful laboratory findings are an elevated serum iron level and high transferrin saturation (more than 60% in men, more than 50% in women). The definitive diagnostic test is a liver biopsy. Recently, a mutation in the \textit{HFE} gene has been shown to occur in most patients with hereditary hemochromatosis (Gochee & Powell, 2001). Patients who are homozygous for the gene are at high risk for development of the disorder.

\section*{Medical Management}

Therapy involves the removal of excess iron via therapeutic phlebectomy (removal of whole blood from a vein). Each unit of blood removed results in a decrease of 200–250 mg of iron. The objective typically is to reduce the serum ferritin to less than 50 μg/L and the transferrin saturation to 35% or less. To achieve this, a frequent phlebotomy schedule is required (1 to 2 units weekly), with a gradual reduction in frequency of phlebotomies over a 1- to 3-year period. After 1 to 3 years, the frequency of phlebotomy can be reduced to 1 unit of blood every several months to prevent reaccumulation of iron deposits. Removal of excess iron appears to diminish the severity of diabetes and skin hyperpigmentation; cardiac function also tends to improve.

\section*{Nursing Management}

Patients with hemochromatosis often believe that it is important to limit their dietary intake of iron, although this management method has been shown to be very ineffective and need not be encouraged. However, it is important for these patients to avoid any additional insults to the liver, such as alcohol abuse. Serial screening tests for hepatoma are important; alpha-fetoprotein is used for this purpose. Other body systems should be monitored for signs of organ dysfunction, particularly the endocrine and cardiac systems. These systems should also be screened routinely for dysfunction so that appropriate management can be implemented quickly. Because patients with hemochromatosis require frequent phlebotomies, problems with venous access are common. Patients who are heterozygous for the \textit{HFE} do not develop the disease but need to be counseled that they can transmit the gene to their children.

\section*{The Polycythemias}

\textbf{Polycythemia} refers to an increased volume of RBCs. It is a term used when the hematocrit is elevated (to more than 55% in males, more than 50% in females). Dehydration (decreased volume of plasma) can cause an elevated hematocrit, but not typically to the level to be considered polycythemia. Polycythemia is classified as either primary or secondary.

\textbf{POLYCYTHEMIA VERA}

Polycythemia vera, or primary polycythemia, is a proliferative disorder in which the myeloid stem cells seem to have escaped normal control mechanisms. The bone marrow is hypercellular, and the RBC, WBC, and platelet counts in the peripheral blood are elevated. However, the RBC elevation is predominant; the hematocrit can exceed 60%. This phase can last for an extended period (10 years or longer). The spleen resumes its embryonic function of hematopoiesis and enlarges. Over time, the bone marrow may become fibrotic, with a resultant inability to produce as many cells ("burnt out" or spent phase). The disease evolves into myeloid metaplasia with myelofibrosis or AML in a significant proportion of patients; this form of AML is usually refractory to standard treatments (Hoffman, et al., 2000). The median survival time exceeds 15 years (Gruppo Italiano Studio Policitemia, 1995).

\section*{Clinical Manifestations}

Patients typically have a ruddy complexion and splenomegaly (enlarged spleen). The symptoms result from the increased blood volume (headache, dizziness, tinnitus, fatigue, paresthesias, and blurred vision) or from increased blood viscosity (angina, claudication, dyspnea, and thrombophlebitis), particularly if the patient has atherosclerotic blood vessels. Another common and bothersome problem is generalized pruritus, which may be caused by histamine release due to the increased number of basophils. Erythromelalgia, a burning sensation in the fingers and toes, may be reported and is only partially relieved by cooling.

\section*{Assessment and Diagnostic Findings}

Diagnosis is made by finding an elevated RBC mass (a nuclear medicine procedure), a normal oxygen saturation level, and an enlarged spleen. Other factors useful in establishing the diagnosis include elevated WBC and platelet counts. The erythropoietin level is not as low as would be expected with an elevated hematocrit; it is normal or only slightly low. Causes of secondary erythrocytosis should not be present (see later discussion).

\section*{Complications}

Patients with polycythemia vera are at increased risk for thromboses resulting in a CVA (brain attack, stroke) or heart attack (MI); thrombotic complications are the most frequent cause of death. Bleeding is also a complication, possibly due to the fact that the platelets (often very large) are somewhat dysfunctional. The bleeding can be significant and can occur in the form of nosebleeds, ulcers, and frank gastrointestinal bleeding.

\section*{Medical Management}

The objective of management is to reduce the high blood cell mass. Phlebotomy is an important part of therapy and can be performed repeatedly to keep the hematocrit within normal range. This is achieved by removing enough blood (initially 500 mL once or twice weekly) to deplete the patient’s iron stores, thereby rendering the patient iron deficient and consequently unable to continue to manufacture RBCs excessively. Patients need to be instructed to avoid iron supplements, including those within multivitamin supplements. If the patient has an elevated uric acid concentration, allopurinol (Zyloprim) is used to prevent gouty attacks. Antihistamines are not particularly effective in controlling itching. If the patient develops ischemic symptoms, dipyrindamole (eg, Persantine) is sometimes used. Radioactive phosphorus ($^{32}$P) or chemotherapeutic agents (eg, hydroxyurea [Hydrea]) can be used to suppress marrow function, but they may increase the risk for leukemia. Patients receiving hydroxyurea appear to have a lower incidence of thrombotic complications; this may result from a more controlled platelet count. The use of aspirin to prevent thrombotic complications is controversial. Low-dose aspirin is frequently used in patients with cardiovascular disease, but even this dose is often avoided in patients with prior bleeding, especially bleeding from the gastrointestinal tract. Aspirin
Neutropenia (neutrophils less than 2000/mm³) results from decreased production of neutrophils or increased destruction of these cells (Chart 33-5). Neutrophils are essential in preventing and limiting bacterial infection. A patient with neutropenia is at increased risk for infection, both exogenous and endogenous (the gastro-intestinal tract and skin are common endogenous sources). The risk for infection is based not only on the severity of the neutropenia (low neutrophil count), but also on the duration of the neutropenia. The actual number of neutrophils, known as the absolute neutrophil count (ANC), is determined by a simple mathematical calculation using data obtained from the CBC and differential test (Chart 33-6). The risk of infection increases proportionately with the decrease in neutrophil count. The risk is significant when the ANC is less than 1000, is high when it is less than 500, and is almost certain when it is less than 100. The risk

### Causes of Neutropenia

**Decreased Production of Neutrophils**
- Aplastic anemia, due to medications or toxins
- Metastatic cancer, lymphoma, leukemia
- Myelodysplastic syndromes
- Chemotherapy
- Radiation therapy

**Ineffective Granulopoiesis**
- Megaloblastic anemia

**Increased Destruction of Neutrophils**
- Hypersplenism
- Medication-induced
- Immunologic disease (eg, systemic lupus erythematosus [SLE])
- Viral disease (eg, infectious hepatitis, mononucleosis)
- Bacterial infections

*Formation of antibody to medication, leading to a rapid decrease in neutrophils.

### Calculating the Absolute Neutrophil Count (ANC)

\[
ANC = \frac{\text{Total WBC count} \times (\% \text{ neutrophils} + \% \text{ bands})}{100}
\]

Normally, the neutrophil count is greater than 2000/mm³. The actual (or absolute) neutrophil count (ANC) is calculated using the above formula.

For example, if the total white blood cell (WBC) count is 3000/mm³ with 72% neutrophils and 3% bands, the ANC would be calculated as follows:

\[
ANC = \frac{3000(72 + 3)}{100} = 2250
\]

This result is not indicative of neutropenia, because the ANC is greater than 2000 despite the low total WBC count (3000/mm³).

Conversely, in the following example, neutropenia is evident despite a normal WBC count (5500/mm³) with 8% neutrophils and 0% bands:

\[
ANC = \frac{5500(8 + 0)}{100} = 440
\]

Here, the ANC is severely low (440) despite the normal total WBC count (5500/mm³).

When evaluating neutropenia, it is important to calculate the ANC and not to rely solely on the total WBCs and percentage of neutrophils alone.
of developing infection increases with the length of time during which neutropenia persists, even if it is fairly mild. Conversely, even a severe neutropenia may not result in infection if the duration of the neutropenia is brief, as is often seen after chemotherapy (Chart 33-7).

Clinical Manifestations

There are no definite symptoms of neutropenia until the patient becomes infected. Routine CBC with differential tests, such as those obtained after chemotherapy treatment, can reveal neutropenia before the onset of infection.

Medical Management

Treatment of the neutropenia varies depending on its cause. If the neutropenia is medication induced, the offending agent needs to be stopped, if possible. Treatment of an underlying neoplasm can temporarily make the neutropenia worse, but with bone marrow recovery treatment may improve it. Corticosteroids may be used if the cause is an immunologic disorder. The use of growth factors such as G-CSF or granulocyte/macrophage colony-stimulating factor (GM-CSF) can be effective in increasing neutrophil production when the cause of the neutropenia is decreased production. Withholding or reducing the dose of chemotherapy or radiation therapy may be required when the neutropenia is caused by these treatments; however, in the case of potentially curative therapy, administration of growth factor is considered to be preferable, so that the maximum antitumor effect can be achieved. Should the neutropenia be accompanied by fever, the patient is automatically considered to be infected and usually is admitted to the hospital. Cultures of blood, urine, and sputum should be obtained, as well as a chest radiograph. To ensure adequate therapy against the invading infectious organisms, broad-spectrum antibiotics are initiated as soon as the samples for culture are obtained, although the medications may be changed after culture and sensitivity results become available.

Nursing Management

Nurses in all settings have a crucial role in assessing the severity of neutropenia and in preventing and managing infectious complications. Patient teaching is equally important, particularly in the outpatient setting, so that the patient can implement appropriate self-care measures and know when and how to seek medical care (Chart 33-8). Patients at risk for neutropenia should have blood drawn for CBCs; the frequency is based on the suspected severity and duration of the neutropenia. Nurses need to be able to calculate the ANC (see Chart 33-6) and to assess the severity of neutropenia and the risk for infection. Chart 33-9 identifies nursing interventions related to neutropenia.

Leukocytosis and the Leukemias

The term leukocytosis refers to an increased level of WBCs in the circulation. Typically, only one specific cell type is increased. Usually, because the proportions of several types of WBCs are small (eg, eosinophils, basophils, monocytes), only an increase in neutrophils or lymphocytes can be great enough to elevate the total WBC count. Although leukocytosis can be a normal response to increased need (eg, in acute infection), the elevation in WBCs should decrease as the need decreases. A prolonged or progressively increasing elevation in WBCs is abnormal and should be evaluated. A significant cause for persistent leukocytosis is malignancy.

Hematopoiesis is characterized by a rapid, continuous turnover of cells. Normally, production of specific blood cells

**Concurrent medications**: See text
from their stem cell precursors is carefully regulated according to the body’s needs. If the mechanisms that control the production of these cells are disrupted, the cells can proliferate to an excessive, potentially dangerous degree. Hematopoietic malignancies are often classified according to the cells involved. Leukemia, literally “white blood,” is a neoplastic proliferation of one particular cell type (granulocytes, monocytes, lymphocytes, or megakaryocytes). The defect originates in the hematopoietic stem cell, the myeloid, or the lymphoid stem cell. The lymphomas are neoplasms of lymphoid tissue, usually derived from B lymphocytes. Multiple myeloma is a malignancy of the most mature form of B lymphocyte, the plasma cell.

The common feature of the leukemias is an unregulated proliferation of WBCs in the bone marrow. In acute forms (or late stages of chronic forms), the proliferation of leukemic cells leaves little room for normal cell production. There can also be a proliferation of cells in the liver and spleen (extramedullary hematopoiesis). With acute forms, there can be infiltration of other organs, such as the meninges, lymph nodes, gums, and skin. The cause of leukemia is not fully known, but there is some evidence that genetic influence and viral pathogenesis may be involved. Bone marrow damage from radiation exposure or from chemicals such as benzene and alkylating agents (eg, melphalan [Alkeran]) can cause leukemia.

The leukemias are commonly classified according to the stem cell line involved, either lymphoid or myeloid. They are also classified as either acute or chronic, based on the time it takes for symptoms to evolve and the phase of cell development that is halted (ie, with few WBCs differentiating beyond that phase).

In acute leukemia, the onset of symptoms is abrupt, often occurring within a few weeks. WBC development is halted at the blast phase, so that most WBCs are undifferentiated or are blasts. Acute leukemia progresses very rapidly; death occurs within weeks to months without aggressive treatment. In chronic leukemia, symptoms evolve over a period of months to years, and the majority of WBCs produced are mature. Chronic leukemia progresses more slowly; the disease trajectory can extend for years.

ACUTE MYELOID LEUKEMIA (AML)

AML results from a defect in the hematopoietic stem cell that differentiates into all myeloid cells: monocytes, granulocytes (neutrophils, basophils, eosinophils), erythrocytes, and platelets. All age groups are affected; the incidence rises with age, with a peak incidence at age 60 years. AML is the most common nonlymphocytic leukemia.

The prognosis is highly variable and is not consistently based on patient or disease variables. Patients with AML have a potentially curable disease. However, patients who are older or have a more undifferentiated form of AML tend to have a worse prognosis. Those who have preexisting MDS or who had previously received alkylating agents for cancer (secondary AML) have a much worse prognosis; the leukemia tends to be more resistant to treatment, resulting in a much shorter duration of remission. With treatment, these patients survive an average of less than 1 year, with death usually a result of infection or hemorrhage. Patients receiving supportive care also usually survive less than 1 year, again dying from infection or bleeding.

Clinical Manifestations

Most of the signs and symptoms evolve from insufficient production of normal blood cells. Fever and infection result from neutropenia, weakness and fatigue from anemia, and bleeding tendencies from thrombocytopenia. The proliferation of leukemic cells within organs leads to a variety of additional symptoms: pain from an enlarged liver or spleen, hyperplasia of the gums, and bone pain from expansion of marrow.

Assessment and Diagnostic Findings

The disorder develops without warning, with symptoms occurring over a period of weeks to months. CBC results show a decrease in both erythrocytes and platelets. Although the total leukocyte count can be low, normal, or high, the percentage of normal cells is usually vastly decreased. A bone marrow analysis shows an ex-
this leukemia often have significantly more problems with bleed-

cess of immature blast cells (more than 30%). AML can be further
classified into seven different subgroups, based on cytogenetics,
histology, and morphology (appearance) of the blasts. The actual
prognosis varies somewhat between subgroups, but the clinical
course and treatment differ substantially with only one subtype,
acute promyeloctye leukemia (APL, or AML-M3). Patients with
this leukemia often have significantly more problems with bleed-

Complications
Complications of AML include bleeding and infection, the major
causes of death. The risk of bleeding correlates with the level of
platelet deficiency (thrombocytopenia). The low platelet count can result in ecchymoses (bruises) and petechiae (pinpoint red or purple hemorrhagic spots on the skin). Major hemorrhages also may develop when the platelet count drops to less than 10,000/mm³. The most common sites of bleeding are gastrointestinal, pulmonary, and intracranial. For undetermined reasons, fever and infection also increase the likelihood of bleeding.

Because of the lack of mature and normal granulocytes, patients with leukemia are always threatened by infection. The likelihood of infection increases with the degree and duration of neutropenia: neutrophil counts that persist at less than 100/mm³ make the chances of systemic infection extremely high. As the duration of severe neutropenia increases, the patient’s risk for developing fungal infection also increases.

### Medical Management

The overall objective of treatment is to achieve complete remission, in which there is no detectable evidence of residual leukemia remaining in the bone marrow. Attempts are made to achieve remission by the aggressive administration of chemotherapy, called induction therapy, which usually requires hospitalization for several weeks. Induction therapy typically involves high doses of cytarabine (Cytosar, Ara-C) and daunorubicin (DaunoXome) or mitoxantrone (Novantrone) or idarubicin (Idamycin); sometimes etoposide (VP-16, VePesid) is added to the regimen. The choice of agents is based on the patient’s physical status and history of prior antineoplastic treatment.

The aim of induction therapy is to eradicate the leukemic cells, but this is often accompanied by the eradication of normal types of myeloid cells. Thus, the patient becomes severely neutropenic (an ANC of 0 is not uncommon), anemic, and thrombocytopenic (a platelet count of less than 10,000/mm³ is common). During this time, the patient is typically very ill, with bacterial, fungal, and occasionally viral infections, bleeding, and severe mucositis, which causes diarrhea and a marked decline in the ability to maintain adequate nutrition. Supportive care consists of administering blood products (RBCs and platelets) and promptly treating infections. The use of granulocytic growth factors, either G-CSF (filgrastim [Neupogen]) or GM-CSF (sargramostim [Leukine]), can shorten the period of significant neutropenia by stimulating the bone marrow to produce leukocytes more quickly; these agents do not appear to increase the risk of producing more leukemic cells.

When the patient has recovered from the induction therapy (ie, the WBC and platelet counts have returned to normal and any infection has resolved), the patient typically receives consolidation therapy (postremission therapy). The goal of consolidation therapy is to eliminate any residual leukemia cells that are not clinically detectable, thereby diminishing the chance for recurrence. Multiple treatment cycles of various agents are used, usually containing some form of cytarabine (eg, Cytosar, Ara-C). Frequently, the patient receives one cycle of treatment that is almost the same, if not identical, to the induction treatment but uses lower dosages (therefore resulting in less toxicity).

Despite the aggressive use of chemotherapy, the likelihood of remaining in remission for a prolonged period is not great. About 70% of patients with AML experience a relapse (Hiddemann & Buchner, 2001). A recent study of long-term survival of patients with AML found that only 11% survived 10 years or longer (Micallef et al., 2001).

Another aggressive treatment option is bone marrow transplantation (BMT) or peripheral blood stem cell transplantation (PBSCT). When a suitable tissue match can be obtained, the patient embarks on an even more aggressive regimen of chemotherapy (sometimes in combination with radiation therapy), with the treatment goal of destroying the hematopoietic function of the patient’s bone marrow. The patient is then “rescued” with the infusion of the donor stem cells to reinitiate blood cell production. Patients who undergo PBSCT transplantation have a significant risk for problems with infection, potential graft-versus-host disease (in which the donor’s lymphocytes [graft] recognize the patient’s body as “foreign” and set up reactions to attack the “foreign” host), and other complications, PBSCT has been shown to cure AML in 25% to 50% of patients who are at high risk for relapse or who have relapsed (Radich & Sievers, 2000).

Recent advances in understanding of the molecular biology of myeloid blast cells have resulted in a new therapeutic option. After the uncommitted stem cell differentiates into a myeloid stem cell, it expresses a specific antigen on the cell surface, called CD33. It appears that 90% of blast cells found in AML express CD33; normal hematopoietic stem cells do not express this antigen (Radich & Sievers, 2000). Armed with that discovery, researchers developed a monoclonal antibody to target cells with the CD33 antigen. The anti-CD33 antibody is linked to a potent antitumor antibiotic, calicheamicin; this medication is called gemtuzumab ozogamicin (Mylotarg). When administered, the anti-CD33 antibody binds to cells with CD33 antigens, and the calicheamicin causes cell death. Normal myeloid and megakaryocyte precursor have the CD33 antigen, so the Mylotarg destroys them. Patients develop severe neutropenia and thrombocytopenia after receiving this medication. Nonetheless, Mylotarg shows promise as an effective agent against AML. In elderly patients, it appears to be somewhat less toxic than conventional induction therapy regimens.

Another important option for the patient to consider is supportive care alone. In fact, supportive care may be the only option if the patient has significant comorbidity, such as extremely poor cardiac, pulmonary, renal, or hepatic function. In such cases, aggressive antileukemia therapy is not used; occasionally, hydroxyurea (eg, Hydrea) may be used briefly to control the increase of blast cells. Patients are more commonly supported with antimicrobial therapy and transfusions as needed. This treatment approach provides the patient with some additional time at home; however, death frequently occurs within months, typically from infection or bleeding.

### Complications of Treatment

The massive leukemic cell destruction from chemotherapy results in release of electrolytes and fluids within the cell into the systemic circulation. Increases in uric acid levels, potassium, and phosphate are seen; this process is referred to as tumor lysis syndrome (see Chap. 16). The increased uric acid and phosphorus levels make patients vulnerable to renal stone formation and renal colic, which can progress to acute renal failure. Hyperkalemia and hypocalcemia can lead to cardiac dysrhythmias, hypotension, neuromuscular effects such as muscle cramps, weakness, spasm/tetany, confusion, and seizure. Patients require a high fluid intake, alkalization of the urine, and prophylaxis with allopurinol to prevent crystallization of uric acid and subsequent stone formation. Gastrointestinal problems may result from the infiltration of abnormal leukocytes into the abdominal organs and from the toxicity of the chemotherapeutic agents. Anorexia, nausea, vomiting, diarrhea, and severe mucositis are common. Because of the profound myelosuppressive effects of chemotherapy, significant neutropenia and thrombocytopenia typically result in serious infection and increased risk for bleeding.
Nursing Management

Nursing management of the patient with acute leukemia is discussed at the end of the leukemia section in this chapter.

CHRONIC MYELOID LEUKEMIA

Chronic myeloid leukemia (CML) arises from a mutation in the myeloid stem cell. Normal myeloid cells continue to be produced, but there is a preference for immature (blast) forms. Therefore, a wide spectrum of cell types exists within the blood, from blast forms through mature neutrophils. Because there is an uncontrolled proliferation of cells, the marrow expands into the cavities of long bones (eg, the femur), and cells are also formed in the liver and spleen (extramedullary hematopoiesis), resulting in enlargement of these organs that is sometimes painful. In 90% to 95% of patients with CML, a section of DNA is found to be missing from chromosome 22 (the Philadelphia chromosome [Ph1]); it is, in fact, translocated onto chromosome 9. The specific location of these changes is on the BCR gene of chromosome 22 and the ABL gene of chromosome 9. When these two genes fuse (BCR-ABL gene), they produce an abnormal protein (tyrosine kinase protein) that causes WBCs to divide rapidly. This BCR-ABL gene is present in virtually all patients with this disease. CML is uncommon in people younger than 20 years of age, but the incidence increases with age (median age, 40 to 50 years).

Patients diagnosed with CML in the chronic phase have an overall median life expectancy of 3 to 5 years. During that time, they have very few symptoms and complications from the disease itself. Problems with infections and bleeding are rare. However, once the disease transforms to the acute phase (blast crisis), the overall survival time rarely exceeds several months.

Clinical Manifestations

The clinical picture of CML varies. Many patients are asymptomatic, and leukocytosis is detected by a CBC performed for some other reason. The WBC count commonly exceeds 100,000/mm³. Patients with extremely high WBC counts may be somewhat short of breath or slightly confused due to decreased capillary perfusion to the lungs and brain from leukostasis (the excessive amount of WBCs inhibits blood flow through the capillaries). Patients may complain of an enlarged, tender spleen. The liver may also be enlarged. Some patients have somewhat insidious symptoms, such as malaise, anorexia, and weight loss. Lymphadenopathy is rare. There are three stages in CML: chronic, transformation, and accelerated or blast crisis. Patients have more symptoms and complications as the disease progresses.

Medical Management

Advances in understanding of the pathology of CML at a molecular level have led to dramatic changes in its medical management. An oral formulation of a tyrosine kinase inhibitor, imatinib mesylate (Gleevec) works by blocking signals within the leukemia cells that express the BCR-ABL protein, thus preventing a series of chemical reactions that cause the cell to grow and divide (Tennant, 2001; Goldman & Melo, 2001). Gleevec appears to be more useful in the chronic phase of the illness. In clinical trials, it has been generally well tolerated. Antacids and grapefruit juice may limit drug absorption, and large doses of acetaminophen can cause hepatotoxicity. The long-term effects of Gleevec, its impact on survival, and the optimal length of treatment are being determined.

Conventional therapy depends on the stage of disease. In the chronic phase, the expected outcome is correction of the chromosomal abnormality (ie, conversion of the malignant stem cell population back to normal). Agents that have been used successfully for this purpose are interferon-alfa (Roferon-A) and cytosine, often in combination. These agents are administered daily as subcutaneous injections. This therapy is not benign; many patients cannot tolerate the profound fatigue, depression, anorexia, mucositis, and inability to concentrate. A less aggressive therapeutic approach focuses on reducing the WBC count to a more normal level, but does not alter cytogenetic changes. This goal can be achieved by using oral chemotherapeutic agents, typically hydroxyurea (eg, Hydrea) or busulfan (eg, Myleran). In the case of an extreme leukocytosis at diagnosis (eg, WBC count higher than 300,000/mm³), a more emergent treatment may be required. In this instance, leukopheresis (in which the patient’s blood is removed and separated, with the leukocytes withdrawn, and the remaining blood returned to the patient) can temporarily reduce the number of WBCs. An anthracycline chemotherapeutic agent (eg, daunomycin) may also be used to bring the WBC count down quickly to a safer level, where more conservative therapy can be instituted.

The transformation phase can be insidious, but it marks the process of evolution (or transformation) to the acute form of leukemia (blast crisis). In the transformation phase, the patient may complain of bone pain and may report fevers (without any obvious sign of infection) and weight loss. Even with chemotherapy, the spleen may continue to enlarge. The patient may become more anemic and thrombocytopenic; an increased basophil level is detected by the CBC. Despite its being a myeloid stem cell disease, CML will transform in up to 25% of patients to resemble not AML, but acute lymphoid leukemia (ALL), with lymphoid-appearing blasts (Derderian et al., 1993). Transformation into the acute phase can be gradual or rapid.

In the acute form of leukemia (blast crisis), treatment may resemble induction therapy for acute leukemia, using the same medications as for AML or ALL. Patients whose disease evolves into a “lymphoid” blast crisis are less likely to be able to reenter a chronic phase after induction therapy. For those whose disease evolves into AML, therapy is largely ineffective in achieving a second chronic phase. Life-threatening infections and bleeding occur frequently in this phase. CML is a disease that can potentially be cured with BMT or PBSC. Patients who receive such transplants while still in the chronic phase of the illness tend to have a greater chance for cure than those who receive them in the acute phase. The transplantation procedure may now be considered for otherwise healthy patients who are younger than 70 years of age.

ACUTE LYMPHOCYTIC LEUKEMIA

ALL results from an uncontrolled proliferation of immature cells (lymphoblasts) derived from the lymphoid stem cell. The cell of origin is the precursor to the B lymphocyte in approximately 75% of ALL cases; T-lymphocyte ALL occurs in approximately 25% of ALL cases. The BCR-ABL translocation (see earlier discussion) is found in 20% of ALL blast cells. ALL is most common in young children, with boys affected more often than girls; the peak incidence is 4 years of age. After age 15 years, ALL is relatively uncommon. Increasing age appears to be associated with diminished survival (Nachman, 1999). Because of improvements in therapy for ALL, more than 80% of children survive at least
5 years. Even if relapse occurs, resumption of induction therapy can often achieve a second complete remission. Moreover, BMT may be successful even after a second relapse.

**Clinical Manifestations**

Immature lymphocytes proliferate in the marrow and crowd the development of normal myeloid cells. As a result, normal hematopoiesis is inhibited, resulting in reduced numbers of leukocytes, erythrocytes, and platelets. Leukocyte counts may be either low or high, but there is always a high proportion of immature cells. Manifestations of leukemic cell infiltration into other organs are more common with ALL than with other forms of leukemia and include pain from an enlarged liver or spleen, bone pain, and headache and vomiting (because of meningeal involvement).

**Medical Management**

The expected outcome of treatment is complete remission. Lymphoid blast cells are typically very sensitive to corticosteroids and to vinca alkaloids; therefore, these medications are an integral part of the initial induction therapy. Because ALL frequently invades the central nervous system, prophylaxis with cranial irradiation or intrathecal chemotherapy (eg, methotrexate [FoXel]) or both is an integral part of the treatment plan.

Treatment protocols for ALL tend to be complex, using a wide variety of chemotherapeutic agents. They often include a maintenance phase, when lower doses of medications are given for up to 3 years. Despite the complexity, treatment can be provided in the outpatient setting in some circumstances until severe complications develop.

Infections are common, especially viral infections. The use of corticosteroids to treat ALL increases the patient’s susceptibility to infection. Patients with ALL tend to have a better response to treatment than patients with AML do. BMT or PBSCT offers a chance for prolonged remission or even cure if the illness recurs after therapy.

**Nursing Management**

Nursing management of the patient with acute leukemia is discussed at the end of the leukemia section in this chapter.

**CHRONIC LYMPHOCYTIC LEUKEMIA (CLL)**

CLL is a common malignancy of older adults; two thirds of all patients are older than 60 years of age at diagnosis. It is the most common form of leukemia in the United States and Europe, affecting more than 120,000 people, but is rarely seen in Asia. The average survival time for patients with CLL ranges from 14 years (early stage) to 2.5 years (late stage).

**Pathophysiology**

CLL typically derives from a malignant clone of B lymphocytes (T-lymphocyte CLL is rare). In contrast to the acute forms of leukemia, most of the leukemia cells in CLL are fully mature. It appears that these cells can escape apoptosis (programmed cell death), with the result being an excessive accumulation of the cells in the marrow and circulation. The antigen CD52 is prevalent on the surface of many of these leukemic B cells. The disease is classified into three or four stages (two classification systems are in use). In the early stage, an elevated lymphocyte count is seen and can exceed 100,000/mm³. Because the lymphocytes are small, they can easily travel through the small capillaries within the circulation, and the pulmonary and cerebral complications of leukocytosis (as seen with myeloid leukemias) typically are not found in CLL.

Lymphadenopathy occurs as the lymphocytes are trapped within the lymph nodes. The nodes can become very large and are sometimes painful. Hepatomegaly and splenomegaly then develop.

In later stages, anemia and thrombocytopenia may develop. Treatment is typically initiated in the later stages; earlier treatment does not appear to increase survival. Autoimmune complications can also occur at any stage, as either autoimmune hemolytic anemia or idiopathic thrombocytopenic purpura (ITP). In the autoimmune process, the RES destroys the body’s own RBCs or platelets.

**Clinical Manifestations**

Many patients are asymptomatic and are diagnosed incidentally during routine physical examinations or during the course of treatment for another disease. An increased lymphocyte count (lymphocytosis) is always present. The RBC and platelet counts may be normal or, in later stages of the illness, decreased. Enlargement of lymph nodes (lymphadenopathy) is common; it can be severe and sometimes painful. The spleen can also be enlarged (splenomegaly).

Patients with CLL can develop “B symptoms,” a constellation of symptoms including fevers, drenching sweating (especially at night), and unintentional weight loss. These patients have defects in their humoral and cell-mediated immune systems; therefore, infections are common. The defect in cellular immunity is evidenced by an absent or decreased reaction to skin sensitivity tests (eg, Candida, mumps), which is known as anergy. Problems with life-threatening infections are common. Viral infections, such as herpes zoster, can become widely disseminated.

**Medical Management**

In early stages, CLL may require no treatment. When symptoms are severe (drenching night sweats, painful lymphadenopathy), or when the disease progresses to later stages (with resultant anemia and thrombocytopenia), chemotherapy with corticosteroids and chlorambucil (Leukeran) is often used. Other useful agents include cyclophosphamide (eg, Cytoxan), vincristine (eg, Oncovin), and doxorubicin (eg, Adriamycin). A significant number of patients who do not respond to these medications have achieved remission with fludarabine (Fludara), and this medication is increasingly being used as front-line therapy. The major side effect of fludarabine is prolonged bone marrow suppression, manifested by prolonged periods of neutropenia, lymphopenia, and thrombocytopenia. Patients are then at risk for such infections as Pneumocystis carinii, Listeria, mycobacteria, herpes viruses, and cytomegalovirus (CMV). The monoclonal antibody rituximab (Rituxan) also has efficacy in CLL therapy. It is often used in combination with other chemotherapeutic medications. Research has shown that the monoclonal antibody alemtuzumab (Campath) targets the CD52 antigen commonly found on CLL cells and that it is effective in clearing the marrow and circulation of these cells without affecting the stem cells. Because CD52 is present on both B and T lymphocytes, patients receiving alemtuzumab are at significant risk for infection; prophylactic use of antiviral agents and
antibiotics (eg, trimethoprim and sulfamethoxazole [Septra]) is important and needs to continue for a minimum of 2 months after the patient stops treatment. Because bacterial infections are common in patients with CLL, intravenous treatment with immunoglobulin may be given to selected patients.

**NURSING PROCESS: THE PATIENT WITH ACUTE LEUKEMIA**

**Assessment**

Although the clinical picture varies with the type of leukemia involved as well as the treatment implemented, the health history may reveal a range of subtle symptoms reported by the patient before the problem is manifested by findings on physical examination. Weakness and fatigue are common manifestations, not only of the leukemia but also of the resulting complications of anemia and infection. If the patient is hospitalized, the assessments should be performed daily, or more frequently as warranted. Because the physical findings may be subtle initially, a thorough, systematic assessment incorporating all body systems is essential. For example, a dry cough, mild dyspnea, and diminished breath sounds may indicate a pulmonary infection. However, the infection may not be seen initially on the chest x-ray. The lack of neutrophils delays the inflammatory response against the pulmonary infection, and it is the inflammatory response that causes the x-ray changes. The platelet count can become dangerously low, leaving the patient at risk for significant bleeding. The specific body system assessments are delineated in the neutropenic precautions and bleeding precautions, found in Charts 33-9 and 33-10, respectively. When serial assessments are performed, current findings are compared with previous findings to evaluate improvement or worsening. The nurse also must closely monitor the results of laboratory studies. Flow sheets and spreadsheets are particularly useful in

---

**Chart 33-10**

**Nursing Diagnosis**

Potential bleeding* and injury secondary to thrombocytopenia/altered coagulation due to:

- Malignant invasion in bone marrow
- Bone marrow suppression resulting from chemotherapy (particularly alkylators, antitumor antibiotics, antimetabolites) and radiation therapy
- Hypersplenism
- Disseminated intravascular coagulation (DIC)
- Altered coagulation

**Assessment Patient**

Assess the following areas thoroughly every shift or visit (with spot checks throughout the shift if patient is hospitalized), and notify physician if there is new onset of the following and/or worsening of status:

- **Integument:** Petechiae (usually located on trunk, thighs), ecchymoses or hematomas, conjunctival hemorrhages, bleeding gums, bleeding at puncture sites (venipuncture, lumbar puncture, bone marrow)
- **Cardiovascular:** Hypotension, tachycardia, complaints of dizziness, epistaxis
- **Pulmonary:** Respiratory distress, tachypnea
- **Gastrointestinal:** Hemoptysis, abdominal distention, rectal bleeding
- **Genitourinary:** Vaginal or urethral bleeding
- **Neurologic:** Headache, blurred vision, mental status changes

**Laboratory Tests**

- Monitor complete blood count (CBC), platelets daily (at least); coagulation panel.
- Notify physician if platelet count is <10,000/mm³ or if count has changed significantly from previous count (including coagulation), or whenever patient becomes symptomatic.
- Ensure patient’s blood was human leukocyte antigen (HLA) typed before transfusions or chemotherapy begins if admitted for induction therapy (eg, for acute leukemia).
- Obtain 1-hour posttransfusion platelet count if warranted.
- Test all urine, emesis, stools for occult blood.

---

**Nursing Interventions**

**Prevent Complications**

- Avoid aspirin and aspirin-containing medications or other medications known to inhibit platelet function, if possible.
- Do not give intramuscular injections.
- Do not insert indwelling catheters.
- Take no rectal temperatures; do not give suppositories, enemas.
- Use stool softeners, oral laxatives to prevent constipation.
- Use smallest possible needles when performing venipuncture.
- Apply pressure to venipuncture sites for 5 min or until bleeding has stopped.
- Permit no flossing of teeth and no commercial mouthwashes.
- Use only soft-bristled toothbrush for mouth care.
- Use only toothettes for mouth care if platelet count is <10,000/mm³, or if gums bleed.
- Lubricate lips with water-soluble lubricant every 2 hr while awake.
- Avoid suctioning if at all possible; if unavoidable, use only gentle suctioning.
- Discourage vigorous coughing or blowing of the nose.
- Use only electric razor for shaving.
- Pad side rails as needed.
- Prevent falls by ambulating with patient as necessary.

**Control Bleeding**

- Apply direct pressure.
- For epistaxis, position patient in high Fowler’s position; apply ice pack to back of neck and direct pressure to nose.
- Notify physician for prolonged bleeding (eg, unable to stop within 10 min).
- Administer platelets, fresh frozen plasma, packed red blood cells, as prescribed.

**Evaluation and Expected Patient Outcomes**

- Patient demonstrates an absence of bleeding as evidenced by absence of spontaneous petechiae, ecchymoses, epistaxis, hemoptysis, bleeding gums, conjunctival hemorrhage, vaginal bleeding, hematuria, guaiac positive stool, blurred vision, orthostatic hypotension, and prolonged bleeding from puncture sites.
- Patient demonstrates an absence of bleeding as evidenced by the presence of vital signs within normal limits and intact neurologic status.

---

*Serious hemorrhage is unusual in mildly thrombocytopenic patients in absence of local lesions (peptic ulcer, bleeding from hemorrhoids, cystitis).
tracking the WBC count, ANC, hematocrit, platelet, and creatinine levels, hepatic function tests, and electrolyte levels. Culture results need to be reported immediately so that appropriate antimicrobial therapy can begin or be modified.

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses for the patient with acute leukemic may include:

- Risk for infection and bleeding
- Risk for impaired skin integrity related to toxic effects of chemotherapy, alteration in nutrition, and impaired mobility
- Impaired gas exchange
- Impaired mucous membranes due to changes in epithelial lining of the gastrointestinal tract from chemotherapy or prolonged use of antimicrobial medications
- Imbalanced nutrition, less than body requirements, related to hypermetabolic state, anorexia, mucositis, pain, and nausea
- Acute pain and discomfort related to mucositis, WBC infiltration of systemic tissues, fever, and infection
- Hyperthermia related to tumor lysis and infection
- Fatigue and activity intolerance related to anemia and infection
- Impaired physical mobility due to anemia and protective isolation
- Risk for excess fluid volume related to renal dysfunction, hypoproteinemia, need for multiple intravenous medications and blood products
- Diarrhea due to altered gastrointestinal flora, mucosal denudation
- Risk for deficient fluid volume related to potential for diarrhea, bleeding, infection, and increased metabolic rate
- Self-care deficit due to fatigue, malaise, and protective isolation
- Anxiety due to knowledge deficit and uncertain future
- Disturbed body image related to change in appearance, function, and roles
- Grieving related to anticipatory loss and altered role functioning
- Potential for spiritual distress
- Deficient knowledge about disease process, treatment, complication management, and self-care measures

COLLABORATIVE PROBLEMS/
POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications that may develop include:

- Infection
- Bleeding
- Renal dysfunction
- Tumor lysis syndrome
- Nutritional depletion
- Mucositis

Planning and Goals

The major goals for the patient may include absence of complications and pain, attainment and maintenance of adequate nutrition, activity tolerance, ability for self-care and to cope with the diagnosis and prognosis, positive body image, and an understanding of the disease process and its treatment.

Nursing Interventions

PREVENTING OR MANAGING INFECTION AND BLEEDING

The nursing interventions related to diminishing the risk for infection and for bleeding are delineated in Charts 33-9 and 33-10.

MANAGING MUCOSITIS

Although emphasis is placed on the oral mucosa, it is important to realize that the entire gastrointestinal mucosa can be altered, not only by the effects of chemotherapy but also from prolonged administration of antibiotics. Assessment of the oral mucosa must be thorough; therefore, dentures must be removed. Areas to assess include the palate, buccal mucosa, tongue, gums, lips, oropharynx, and the area under the tongue. In addition to identifying and describing lesions, the color and moisture of the mucosa should be noted.

Oral hygiene is very important to diminish the bacteria within the mouth, maintain moisture, and provide comfort. Soft-bristled toothbrushes should be used until the neutrophil and platelet counts become very low; at that time, sponge-tipped applicators should be substituted. Lemon-glycerin swabs and commercial mouthwashes should never be used because the glycerin and alcohol within them are extremely drying to the tissues. Simple rinses with saline (or saline and baking soda) solutions are inexpensive but effective in cleaning and moistening the oral mucosa. Because the risk of yeast or fungal infection in the mouth is great, other medications are often prescribed, such as chlorhexidine rinses (eg, Peridex) or clotrimazole troches (eg, Mycelex). The nurse reminds the patient about the importance of these medications to enhance adherence to the therapeutic regimen. Chlorhexidine rinses may discolor the teeth.

To diminish perineal–rectal complications, it is important to cleanse the perineal–rectal area thoroughly after each bowel movement. Women are instructed to cleanse the perineum from front to back. Sitz baths are a comfortable method of cleansing; the perineal–anal region and buttocks must be carefully dried afterward to minimize the chance of excoriation. Stool softeners should be used to increase the moisture of bowel movements; however, the stool texture must be monitored so that the softeners can be decreased or stopped if the stool becomes too loose.

IMPROVING NUTRITIONAL INTAKE

The disease process can increase, and sepsis further increases, the patient’s metabolic rate and nutritional requirements. Nutritional intake is often reduced because of pain and discomfort associated with stomatitis. Mouth care before and after meals and administration of analgesics before eating can help increase intake. If oral anesthetics are used, the patient must be warned to chew with extreme care to avoid inadvertently biting the tongue or buccal mucosa.

Nausea should not be a major contributing factor, because recent advances in antiemetic therapy are highly effective. However, nausea can result from antimicrobial therapy, so some antiemetic therapy may still be required after the chemotherapeutic has been completed.

Small, frequent feedings of foods that are soft in texture and moderate in temperature may be better tolerated. Low-microbial diets are typically prescribed (avoiding uncooked fruits or vegetables and those without a peelable skin). Nutritional supplements are frequently used. Daily body weights (as well as in-
take and output measurements) are useful in monitoring fluid status.

Calorie counts are useful, as are more formal nutritional assessments. Parenteral nutrition is often required to maintain adequate nutrition.

EASING PAIN AND DISCOMFORT
Recurrent fevers are common in acute leukemia; at times, they are accompanied by shaking chills, which can be severe (rigors). Myalgias and arthralgias can result. Acetaminophen is typically given to decrease fever, but it does so by increasing diaphoresis. Sponging with cool water may be useful, but cold water or ice packs should be avoided because the heat cannot dissipate from constricted blood vessels. Bedclothes need frequent changing as well. Gentle back and shoulder massage may provide comfort.

Stomatitis can also cause significant discomfort. In addition to oral hygiene practices, patient-controlled analgesia can be effective in controlling the pain (see Chap. 13).

Because patients with acute leukemia require hospitalization for extensive nursing care (either during induction or consolidation therapy or during resultant complications), sleep deprivation frequently results. Nurses need to implement creative strategies that permit uninterrupted sleep for at least a few hours while still administering necessary medications on time.

With the exception of severe mucositis, less pain is associated with acute leukemia than with many other forms of cancer. However, the amount of psychologic suffering that the patient must endure can be immense. Patients greatly benefit from active listening.

DECREASING FATIGUE AND DECONDITIONING
Fatigue is a common and oppressive problem. Nursing interventions should focus on assisting the patient to establish a balance between activity and rest. Patients with acute leukemia need to maintain some physical activity and exercise to prevent the deconditioning that results from inactivity. Use of a high-efficiency particulate air (HEPA) filter mask can permit the patient to ambulate outside the room despite severe neutropenia. Although many patients lack the motivation to use them, stationary bicycles within the room can also be used. At a minimum, patients should be encouraged to sit up in a chair while awake rather than staying in bed; even this simple activity can improve the patient’s tidal volume and enhance circulation. Physical therapy can also be beneficial.

MAINTAINING FLUID AND ELECTROLYTE BALANCE
Febrile episodes, bleeding, and inadequate or overly aggressive fluid replacement can alter the patient’s fluid status. Similarly, persistent diarrhea, vomiting, and long-term use of certain antimicrobial agents can cause significant deficits in electrolytes. In-take and output need to be measured accurately, and daily weights should also be monitored. The patient should be assessed for signs of dehydration as well as fluid overload, with particular attention to pulmonary status and the development of dependent edema. Laboratory test results, particularly electrolytes, blood urea nitrogen, creatinine, and hematocrit, should be monitored and compared with previous results. Replacement of electrolytes, particularly potassium and magnesium, is commonly required. Patients receiving amphotericin or certain antibiotics are at increased risk for electrolyte depletion.

IMPROVING SELF-CARE
Because hygiene measures are so important in this patient population, they must be performed by the nurse when the patient cannot do so. However, the patient should be encouraged to do as much as possible, to preserve mobility and function as well as self-esteem. Patients may have negative feelings, even disgust that they can no longer care for themselves. Empathetic listening is helpful, as is realistic reassurance that these deficits are temporary. As the patient recovers, it is important to assist him or her to resume more self-care. Patients are usually discharged from the hospital with a central vascular access device (e.g., Hickman catheter, PICC), and most patients can care for the catheter with adequate instruction and practice under observation.

MANAGING ANXIETY AND GRIEF
Being diagnosed with acute leukemia can be extremely frightening. In many instances, the need to begin treatment is emergent, and patients have little time to process the fact that they have the illness before making decisions about therapy. Providing emotional support and discussing the uncertain future are crucial. The nurse also needs to assess how much information patients want to have regarding the illness, its treatment, and potential complications. This desire should be reassessed at intervals, because needs and interest in information change throughout the course of the disease and treatment. Priorities must be identified so that procedures, assessments, and self-care expectations are adequately explained even to those who do not wish extensive information.

Many patients become depressed and begin to grieve for the losses they feel, such as normal family functioning, professional roles and responsibilities, and social roles, as well as physical functioning. Nurses can assist patients to identify the source of the grief and encourage them to allow time to adjust to the major life changes produced by the illness. Role restructuring, in both family and professional life, may be required. Again, when possible, permitting patients to identify options and to take time making significant decisions regarding such restructuring is helpful.

Discharge from the hospital can also provoke anxiety. Although most patients are extremely eager to go home, they may lack confidence in their ability to manage potential complications and to resume their normal activity. Close communication between nurses across care settings can reassure patients that they will not be abandoned.

ENCOURAGING SPIRITUAL WELL-BEING
Because acute leukemia is a serious, potentially life-threatening illness, the nurse may offer support to enhance the patient’s spiritual well-being. The patient’s spiritual and religious practices should be assessed and pastoral services offered. Throughout the patient’s illness, it is important that the nurse assist the patient to maintain hope. However, that hope should be realistic and will certainly change over the course of the illness. For example, the patient may initially hope to be cured, but with repeated relapses and a change to terminal care the same patient may hope for a quiet, dignified death.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS
Nursing interventions for potential complications were described previously.

PROMOTING HOME AND COMMUNITY-BASED CARE
Teaching Patients Self-Care
Most patients cope better when they have an understanding of what is happening to them. Based on their education, literacy level, and interest, teaching of patient and family should focus on
the disease (including some pathophysiology), its treatment, and certainly the significant risk for infection and bleeding (Charts 33-8 and 33-11) that results.

Management of a vascular access device can be taught to most patients or family members. Follow-up and care for the devices may also need to be provided by nurses in an outpatient setting or by a home care agency or a health care provider.

Continuing Care. Shortened hospital stays and outpatient care have significantly altered care for patients with acute leukemia. In many instances, when the patient is clinically stable but still requires parenteral antibiotics or blood products, these procedures can be performed in an outpatient setting. Nurses in these various settings must communicate regularly. Patients need to learn which parameters are important for them to monitor, and how to monitor them. Specific instructions need to be given as to when the patient should seek care from the physician or a health care provider.

Patients and their families need to have a clear understanding of the disease and the prognosis. The nurse acts as an advocate to ensure that this information is provided. When patients no longer respond to therapy, it is important to respect their choices about treatment, including measures to prolong life and other end-of-life measures. Advance directives and living wills provide patients with some measure of control during terminal illness.

Many patients in this stage still choose to be cared for at home, and families often need support when considering this option. Coordination of home care services and instruction can help to alleviate anxiety about managing the patient’s care in the home. As the patient becomes weaker, the caregivers must assume more of the patient’s care. In addition, caregivers often need to be encouraged to take care of themselves, allowing time for rest and accepting emotional support. Hospice staff can assist in providing respite for family members as well as care for the patient. Patients and families also need assistance to cope with changes in their roles and responsibilities. Anticipatory grieving is an essential task during this time (see Chap. 17).

In patients with acute leukemia, death typically occurs from infection or bleeding. Family members need to have information about these complications and the measures to take should either occur. Many family members cannot cope with the care required when a patient begins to bleed actively. It is important to delineate alternatives to keeping the patient at home. Should another option be sought, family members who may feel guilty that they could not keep the patient at home will require support from the nurse.

**Evaluation**

**EXPECTED PATIENT OUTCOMES**

Expected patient outcomes may include:

1. Shows no evidence of infection
2. Experiences no bleeding
3. Has intact oral mucous membranes
   a. Participates in oral hygiene regimen
   b. Reports no discomfort in mouth
4. Attains optimal level of nutrition
   a. Maintains weight with increased food and fluid intake
   b. Maintains adequate protein stores (albumin)
5. Reports satisfaction with pain and discomfort levels
6. Has less fatigue and increased activity
7. Maintains fluid and electrolyte balance
8. Participates in self-care
9. Copes with anxiety and grief
   a. Discusses concerns and fears
   b. Uses stress management strategies appropriately
   c. Participates in decisions regarding end-of-life care
10. Absence of complications

**AGNOGENIC MYELOID METAPLASIA (AMM)**

Agnogenic myeloid metaplasia (AMM), also known as myelofibrosis, is a chronic myeloproliferative disorder that arises from neoplastic transformation of an early hematopoietic stem cell. The disease is characterized by marrow fibrosis or scarring, splenomegaly, extramedullary hematopoiesis (typically spleen, liver, or both), leukocytosis and thrombocytosis, and anemia. Some patients have suppressed WBC and platelet counts as well as anemia (pancytopenia). Patients with AMM have increased angiogenesis (formation of new blood vessels) within the marrow. Early forms of blood cells (including nucleated RBCs and megakaryocyte fragments) are frequently found in the circulation. AMM is a disease of the elderly, with a median age at diagnosis of 60 to 65 years. Survival time varies from as little as 1 year to more than 30 years; the average is 4 to 5 years (Anderson, Hamblin, & Traynor, 1999). Heart failure, complications of marrow failure, and transformation to AML are the common causes of death.
Medical Management

Medical management is directed toward palliation, reducing symptoms related to cytopenias, splenomegaly, and hypermetabolic state. Although one third of anemic patients respond to the combination of an androgen plus a corticosteroid, the primary treatment remains RBC transfusion. Because of the prolonged requirement for RBC transfusion, iron overload is a common problem. Iron chelation therapy should be initiated for those individuals in whom survival is expected to exceed a few years (Anderson Hamblin, Traynor, 1999). Hydroxyurea is often used to control high WBC and platelet counts and to reduce the size of the spleen. Splenic irradiation or splenectomy may also be used to control the massive splenomegaly that can develop. However, both modalities render the patient at significant risk for development of infection. BMT may be a useful treatment modality in younger, otherwise healthy individuals.

Nursing Management

The extent of splenomegaly can be profound in patients with AMM, with enlargement of the spleen that extends to the pelvic rim. This condition is extremely uncomfortable to the patient and can severely limit nutritional intake. Analgesics are often ineffective. Methods to reduce the spleen’s size are usually more effective in controlling pain. Splenomegaly, coupled with a hypermetabolic state, results in weight loss (often severe) and muscle wasting. Patients benefit from very small, frequent meals of foods that are high in calories and protein. Weakness, fatigue, and altered body image are other significant problems. Energy conservation methods and active listening are important nursing interventions. Patients need to be educated about signs and symptoms of infection as well as appropriate interventions when an infection is suspected.

The Lymphomas

The lymphomas are neoplasms of cells of lymphoid origin. These tumors usually start in lymph nodes but can involve lymphoid tissue in the spleen, the gastrointestinal tract (eg, the wall of the stomach), the liver, or the bone marrow. They are often classified according to the degree of cell differentiation and the origin of the predominant malignant cell. Lymphomas can be broadly classified into two categories: Hodgkin’s disease and non-Hodgkin’s lymphoma (NHL).

HODGKIN’S DISEASE

Hodgkin’s disease is a relatively rare malignancy that has an impressive cure rate. It is somewhat more common in men than women and has two peaks of incidence: one in the early 20s and the other after 50 years of age. Unlike other lymphomas, Hodgkin’s disease is unicentric in origin in that it initiates in a single node. The disease spreads by contiguous extension along the lymphatic system. The cause of Hodgkin’s disease is unknown, but a viral etiology is suspected. In fact, fragments of the Epstein-Barr virus have been found in 40% to 50% of patients; this occurs more commonly in the younger patient population (Weiss, 2000). There is a familial pattern associated with Hodgkin’s disease: first-degree relatives have a higher-than-normal frequency of the disease. There is no increased incidence documented for non-blood relatives (eg, spouses).

The malignant cell of Hodgkin’s disease is the Reed-Sternberg cell, a gigantic tumor cell that is morphologically unique and is thought to be of immature lymphoid origin. It is the pathologic hallmark and essential diagnostic criterion for Hodgkin’s disease. However, the tumor is very heterogeneous and may actually contain few Reed-Sternberg cells. Repeated biopsies may be required to establish the diagnosis.

Hodgkin’s disease is customarily classified into five subgroups based on pathologic analyses that reflect the natural history of the malignancy and suggest the prognosis. For example, when lymphocytes predominate, with few Reed-Sternberg cells and minimal involvement of the lymph nodes, the prognosis is much more favorable than when the lymphocyte count is low and the lymph nodes are virtually replaced by tumor cells of the most primitive type. The majority of patients with Hodgkin’s disease have the types currently designated “nodular sclerosis” or “mixed cellularity.” The nodular sclerosis type tends to occur more often in young women, at an earlier stage but with a worse prognosis than the mixed cellularity subgroup, which occurs more commonly in men and causes more constitutional symptoms but has a better prognosis.

Clinical Manifestations

Hodgkin’s disease usually begins as a painless enlargement of one or more lymph nodes on one side of the neck. The individual nodes are painless and firm but not hard. The most common sites for lymphadenopathy are the cervical, supraclavicular, and mediastinal nodes; involvement of the iliac or inguinal nodes or spleen is much less common. A mediastinal mass may be seen on chest x-ray; occasionally, the mass is large enough to compress the trachea and cause dyspnea. Pruritus is common; it can be extremely distressing, and the cause is unknown. Approximately 20% of patients experience brief but severe pain after drinking alcohol (Cavalli, 1998). The pain is usually at the site of the Hodgkin’s disease; again, the cause is unknown.

All organs are vulnerable to invasion by Hodgkin’s disease. The symptoms result from compression of organs by the tumor, such as cough and pulmonary effusion (from pulmonary infiltrates), jaundice (from hepatic involvement or bile duct obstruction), abdominal pain (from splenomegaly or retroperitoneal adenopathy), or bone pain (from skeletal involvement). Herpes zoster infections are common. A cluster of constitutional symptoms has important prognostic implications. Referred to as “B symptoms,” they include fever (without chills), drenching sweats (particularly at night), and unintentional weight loss of more than 10%. “B symptoms” are found in 40% of patients and are more common in advanced disease.

A mild anemia is the most common hematologic finding. The WBC count may be elevated or decreased. The platelet count is typically normal, unless the tumor has invaded the bone marrow, suppressing hematopoiesis. The erythrocyte sedimentation rate (ESR) and the serum copper level are used by some clinicians to assess disease activity. Patients with Hodgkin’s disease have impaired cellular immunity, as evidenced by an absent or decreased reaction to skin sensitivity tests (eg, Candida, mumps).

Assessment and Diagnostic Findings

Because many manifestations are similar to those occurring with infection, diagnostic studies are performed to rule out an infectious origin for the disease. The diagnosis is made by means of an excisional lymph node biopsy and the finding of the Reed-Sternberg cell. Once the diagnosis is confirmed and the histologic type is established, it is necessary to assess the extent of the disease, a process referred to as staging.
During the health history, the nurse should assess for any “B symptoms.” Physical examination requires a careful, systematic evaluation of the lymph node chains, as well as the size of the spleen and liver. A chest x-ray and a CT scan of the chest, abdomen, and pelvis are crucial to identify the extent of lymphadenopathy within these regions. Laboratory tests include CBC, platelet count, ESR, and liver and renal function studies. A bone marrow biopsy is performed if there are signs of marrow involvement, and some physicians routinely perform bilateral biopsies. Bone scans may be performed to identify any involvement in these areas. A staging laparotomy and lymphangiography are no longer considered mandatory, primarily because of the accuracy of CT.

**Medical Management**

The general intent in treating Hodgkin’s disease, regardless of stage, is cure. Treatment is determined primarily by the stage of the disease, not the histologic type; however, extensive research is ongoing to target treatment regimens to histologic subtypes or prognostic features. Traditionally, early Hodgkin’s disease was treated by a staging laparotomy followed by radiation therapy. Recent data show improved results and decreased complications with a short course (2 to 4 months) of chemotherapy followed by radiation therapy in certain subsets of early-stage disease (IA and IIA); patients with early-stage disease and good prognostic features may receive radiation therapy alone (Hoppe et al., 2000). Combination chemotherapy, for example with doxorubicin (Adriamycin), bleomycin (Blenoxane), vinblastine (Velban), and dacarbazine (DTIC), referred to as ABVD, is now the standard treatment for more advanced disease (stages III and IV and all B stages).

Radiation therapy is still very useful for patients with extensive adenopathy (often termed bulky disease). In this group, residual disease often persists after the chemotherapy treatment is finished; radiation therapy to the areas of remaining adenopathy has been shown to improve survival.

Even when Hodgkin’s disease does recur, the use of high doses of chemotherapeutic agents, followed by autologous BMT or stem cell transplantation (PBSCST), can be very effective in controlling the disease and extending survival time.

**Long-Term Complications of Therapy**

Much is now known about the long-term effects of chemotherapy and radiation therapy, primarily from the large numbers of people who were cured of Hodgkin’s disease by these treatments. The various complications of treatment are listed in Chart 33-12. Risk factors for other cancers should be assessed, and long-term surveillance is crucial. The potential development of a second malignancy is obviously of concern to patients, and this potential should be addressed with the patient when treatment decisions are made. However, it is important to consider that Hodgkin’s disease is curable. Revised treatment approaches are aimed at diminishing the risk for complications without sacrificing the potential for cure.

**NON-HODGKIN’S LYMPHOMAS (NHLs)**

The NHLs are a heterogeneous group of cancers that originate from the neoplastic growth of lymphoid tissue. As in CLL, the neoplastic cells are thought to arise from a single clone of lymphocytes; however, in NHL, the cells may vary morphologically. Most NHLs involve malignant B lymphocytes; only 5% involve T lymphocytes. In contrast to Hodgkin’s disease, the lymphoid tissues involved are largely infiltrated with malignant cells. The spread of these malignant lymphoid cells occurs unpredictably, and true localized disease is uncommon. Lymph nodes from multiple sites may be infiltrated, as may sites outside the lymphoid system (extranodal tissue).

The incidence of NHL has increased dramatically over the past decade; it is now the fourth most common type of cancer diagnosed in the United States and the fifth most common cause of cancer death (Greenlee, Hill-Horton, Murray, & Thun, 2001; Zelenetz et al., 2000). The incidence increases with each decade of life; the average age at diagnosis is 50 to 60 years. Although no common etiologic factor has been identified, there is an increased incidence of NHL in people with immunodeficiencies or autoimmune disorders, viral infections (including Epstein-Barr virus and HIV), or exposure to pesticides, solvents, or dyes. Prognosis varies greatly among the various types of NHL. Long-term survival (more than 10 years) is commonly achieved in low-grade, localized lymphomas. Even with aggressive disease forms, cure is possible in at least one third of patients who receive aggressive treatment.

**Clinical Manifestations**

Symptoms are highly variable, reflecting the diverse nature of these diseases. With early-stage disease, or with the types that are considered more indolent, symptoms may be virtually absent or very minor, and the illness typically is not diagnosed until it progresses to a later stage, when the patient is more symptomatic. At these stages (III or IV), lymphadenopathy is noticeable. One third of patients have “B symptoms” (recurrent fever, drenching night sweats, and unintentional weight loss of 10% or more).

**Assessment and Diagnostic Findings**

The actual diagnosis of NHL is categorized into a highly complex classification system based on histopathology, immunophenotyping, and cytogenetic analyses of the malignant cells. The specific histopathologic type of the disease has important prognostic implications. Treatment also varies and is based on these features. Indolent (less aggressive) types tend to have small cells and are distributed in a follicular pattern. Aggressive types tend to have...
large or immature cells distributed through the nodes in a diffuse pattern. Staging, also an important factor, is typically based on data obtained from CT scans, bone marrow biopsies, and occasionally cerebrospinal fluid analysis. The stage is based on the site of disease and its spread to other sites. For example, in stage I disease, only one area of involvement is detected; thus, stage I disease is highly localized and may respond well to localized therapy (eg, radiation therapy). In contrast, stage IV disease is detected in at least one extranodal site. Although low-grade lymphomas may not require treatment until the disease progresses to a later stage, historically they have also been relatively unresponsive to treatment in that most therapeutic modalities did not improve overall survival. More aggressive types of NHL (eg, lymphoblastic lymphoma, Burkitt’s lymphoma) require prompt initiation of chemotherapy; however, these types tend to be more responsive to treatment.

Medical Management

Treatment is based on the actual classification of disease, the stage of disease, prior treatment (if any), and the patient’s ability to tolerate therapy. If the disease is not an aggressive form and is truly localized, radiation alone may be the treatment of choice. With aggressive types of NHL, aggressive combinations of chemotherapeutic agents are given even in early stages. More intermediate forms are commonly treated with combination chemotherapy and radiation therapy for stage I and II disease. The biologic agent interferon has been approved for the treatment of follicular low-grade lymphomas, and an antibody to CD20, rituximab (Rituxan), has been effective in achieving partial responses in patients with recurrent low-grade lymphoma. Studies of this agent in combination with conventional chemotherapy have demonstrated an improvement in survival as well (Coiffier, 2002; Emmanouilides et al., 2000; Petryk & Grossbard, 2000). Central nervous system involvement is also common with some aggressive forms of NHL; in this situation, cranial radiation or intrathecal chemotherapy is used in addition to systemic chemotherapy. Treatment after relapse is controversial. BMT or PBSC may be considered for patients younger than 60 years of age (See Chap. 16).

Nursing Management

Most of the care for patients with Hodgkin’s disease or NHL is performed in the outpatient setting, unless complications occur (eg, infection, respiratory compromise due to mediastinal mass). For patients who require treatment, chemotherapy and radiation therapy are most commonly used. Chemotherapy causes systemic side effects (eg, myelosuppression, nausea, hair loss, risk for infection), whereas the side effects from radiation therapy are specific to the area being irradiated. For example, patients receiving abdominal radiation therapy may experience nausea and diarrhea but not hair loss. Regardless of the type of treatment, all patients may experience fatigue.

The risk of infection is significant for these patients, not only from treatment-related myelosuppression but also from the defective immune response that results from the disease itself. Patients need to be taught to minimize the risks for infection, to recognize signs of possible infection, and to contact the health care professional should such signs develop (see Chart 33-8).

Many lymphomas can be cured with current treatments. However, as survival rates increase, the incidence of second malignancies, particularly AML or MDS, also increases. Therefore, survivors should be screened regularly for the development of second malignancies.

Lymphoma is a highly complex constellation of diseases. When caring for the patient with lymphoma, it is extremely important to know the specific disease type, stage of disease, treatment history, and current treatment plan.

MULTIPLE MYELOMA

Multiple myeloma is a malignant disease of the most mature form of B lymphocyte, the plasma cell. It is not classified as a lymphoma. Plasma cells secrete immunoglobulins, proteins necessary for antibody production to fight infection.

Pathophysiology

In myeloma, the malignant plasma cells produce an increased amount of a specific immunoglobulin that is nonfunctional. Functional types of immunoglobulin are still produced by nonmalignant plasma cells, but in lower-than-normal quantity. The specific immunoglobulin secreted by the myeloma cells is detectable in the blood or urine and is referred to as the monoclonal protein, or M protein. This protein serves as a useful marker to monitor the extent of disease and the patient’s response to therapy. It is measured by serum or urine protein electrophoresis. Moreover, the patient’s total protein level is typically elevated, again due to the production of M protein. Malignant plasma cells also secrete certain substances to stimulate the creation of new blood vessels to enhance the growth of these clusters of plasma cells; this process is referred to as angiogenesis. Occasionally the plasma cells infiltrate other tissue, in which case they are referred to as plasmacytomas. Plasmacytomas can occur in the sinuses, spinal cord, and soft tissues. Median survival time is 3 to 5 years. Death usually results from infection.

Clinical Manifestations

The classic presenting symptom of multiple myeloma is bone pain, usually in the back or ribs. Bone pain is reported by two thirds of all patients at diagnosis. Unlike arthritic pain, the bone pain associated with myeloma increases with movement and decreases with rest; patients may report that they have less pain on awakening but the pain intensity increases during the day. In myeloma, a substance secreted by the plasma cells, osteoclast activating factor, as well as other substances (eg, interleukin-6 [IL-6]) are involved in stimulating osteoclasts. Both mechanisms appear to be involved in the process of bone breakdown. Thus, lytic lesions as well as osteoporosis may be seen on bone x-rays. (They are not well visualized on bone scans.) The bone destruction can be severe enough to cause fractures, including spinal fractures, which can impinge on the spinal cord and result in spinal cord compression. It is this bone destruction that causes significant pain.

**NURSING ALERT** Any elderly patient whose chief complaint is back pain, and who has an elevated total protein level, should be evaluated for possible myeloma.

If the bone destruction is fairly extensive, excessive ionized calcium is lost from the bone and enters the serum; patients may therefore become hypercalcemic (frequently manifested by excessive thirst, dehydration, constipation, altered mental status, confusion, and perhaps coma). Renal failure may also be seen; the configuration of the circulating immunoglobulin molecule (particularly the shape of lambda light chains) can damage the renal tubules.
As more and more malignant plasma cells are produced, the marrow has less space for RBC production, and the patient can become anemic. This anemia is also caused to a great extent by a diminished production of erythropoietin (a glycoprotein necessary for RBC production) by the kidney. Patients may complain of fatigue and weakness due to the anemia. In the late stage of the disease, a reduced number of WBCs and platelets may also be seen because the bone marrow is infiltrated by malignant plasma cells.

When plasma cells secrete excessive amounts of immunoglobulin, particularly IgA, the serum viscosity can be elevated. Hyperviscosity may be manifested by bleeding from the nose or mouth, headache, blurred vision, paresthesias, or heart failure.

Assessment and Diagnostic Findings
Finding an elevated monoclonal protein spike in the serum (via serum protein electrophoresis) or urine (via urine protein electrophoresis) or light chain in the urine (sometimes referred to as Bence Jones protein) is considered to be a major criterion in the diagnosis of multiple myeloma. The presence of lytic bone lesions on x-ray aids in the diagnosis, as does the presence of anemia or hypercalcemia. The diagnosis of myeloma can be confirmed by bone marrow biopsy; the presence of sheets of plasma cells is the hallmark diagnostic criterion. Because the infiltration of the marrow by these malignant plasma cells is not uniform, the extent of plasma cells may not be increased in a given sample (a false-negative result).

Gerontologic Considerations
The incidence of multiple myeloma increases with age; the disease rarely occurs in patients younger than 40 years of age. Because of the increasing older population, more patients are seeking treatment for this disease. BMT or PBSCT is an option that can prolong remission and potentially cure some patients. However, it is unavailable to most because of age limitations. Back pain, which is often a presenting symptom in this disease, should be closely investigated in elderly patients.

Medical Management
There is no cure for multiple myeloma. Even BMT or PBSCT is considered by most authorities to extend remission rather than provide a cure. However, for many patients, it is possible to control the illness and maintain their level of functioning quite well for several years or longer. Chemotherapy is the primary treatment; corticosteroids, particularly dexamethasone (Decadron), are especially effective and are often combined with other agents (such as melphalan [Alkeran], cyclophosphamide [Cytoxan], doxorubicin [Adriamycin], vincristine [Oncovin], and BCNU [Carmustine]).

Radiation therapy is very useful in strengthening a specific bone lesion, particularly one at risk for bone fracture or spinal cord compression. It is also useful in relieving bone pain and reducing the size of plasma cell tumors that occur outside the skeletal system. However, because it is a nonsystemic form of treatment, it does not diminish the source of the bone problems (ie, the production of malignant plasma cells). Therefore, radiation therapy is typically used with systemic treatment such as chemotherapy.

The biologic agent alpha-interferon has been used successfully to maintain remission in selected types of myeloma, particularly IgA type; however, its role in prolonging survival is controversial. Newer forms of bisphosphonates, such as pamidronate (Aredia) and zoledronic acid (Zometa), have been shown to strengthen bone in this disease (by diminishing the secretion of osteoclast activating factor) (Terpos et al., 2000), controlling bone pain and potentially preventing bone fracture. They are also effective in managing and preventing hypercalcemia. Some evidence suggests that bisphosphonates may actually have activity against the myeloma cells themselves by inhibiting a growth factor necessary for myeloma cell survival (Berenson, 2001) (see later discussion).

When patients manifest signs and symptoms of hyperviscosity, plasmapheresis may be used to lower the immunoglobulin level. Symptoms may be more useful than serum viscosity levels in determining the need for this intervention.

Recent advances in the understanding of the process of angiogenesis have resulted in new therapeutic options. The sedative thalidomide (Thalomid), initially used as an antiemetic, has significant antmyeloma effects. It inhibits cytokines necessary for new vascular generation, such as, vascular endothelial growth factor (VEGF) and for myeloma cell growth and survival, such as IL-6 and tumor necrosis factor), by boosting the body’s immune response against the tumor and by creating favorable conditions for apoptosis of the myeloma cells. Thalidomide is effective in refractory myeloma and in “smoldering” disease states, and may prevent progression to a more active state. Thalidomide is not a typical chemotherapeutic agent and has a unique side effect profile. Fatigue, dizziness, constipation, rash, and peripheral neuropathy are commonly encountered; myelosuppression is not (Goldman, 2001). Thalidomide is contraindicated in pregnancy because of associated severe birth defects.

Nursing Management
Pain management is very important in this patient population. NSAIDs can be very useful for mild pain, or in combination with opioid analgesics. However, care needs to be taken, because NSAIDs can cause renal dysfunction. Patients need to be educated about activity restrictions (eg, lifting no more than 10 pounds, use of proper body mechanics). Braces are occasionally needed to provide support to the spinal column.

Patients also need to be instructed about the signs and symptoms of hypercalcemia. Maintaining mobility and hydration is important to diminish exacerbations of this complication; however, the primary cause is the disease itself. Renal function should also be monitored closely. Renal failure can become severe, and dialysis may be needed. Maintaining high urine output (3 L/day) can be very useful in preventing this complication.

Because antibody production is impaired, infections, particularly bacterial infections, are common and can be life-threatening. Patients need to be instructed in appropriate infection prevention measures (see Chart 33–8) and should be advised to contact their health care provider immediately if they have a fever or other signs and symptoms of infection. Patients should receive Pneumovax and flu vaccines. Prophylactic antibiotics are sometimes used. Intravenous gamma globulin (IVIG) can be useful for patients with recurrent infections.

Bleeding Disorders
Normal hemostatic mechanisms can control bleeding from vessels and prevent spontaneous bleeding. The bleeding vessel constricts and platelets aggregate at the site, forming an unstable hemostatic plug. Circulating coagulation factors are activated on the surface of these aggregated platelets, forming fibrin, which anchors the platelet plug to the site of injury.
The failure of normal hemostatic mechanisms can result in bleeding, which is severe at times. This bleeding is commonly provoked by trauma, but in certain circumstances it can occur spontaneously. When the source is platelet or coagulation factor abnormalities, the site of spontaneous bleeding can be anywhere in the body. When the defect is caused by vascular abnormalities, the site of bleeding may be more localized. Some patients have defects in more than one hemostatic mechanism simultaneously.

In a variety of situations, the bone marrow may be stimulated to increase platelet production (thrombopoiesis). The increased production may be a reactive response, as in a compensatory response to significant bleeding, or a more general response to increase hematopoiesis, as in iron deficiency anemia. Sometimes, the increase in platelets does not result from increased production but from a loss in platelet pooling within the spleen. The spleen typically holds about one third of the circulating platelets at any time. If the spleen is lost (eg, splenectomy), the platelet reservoir is also lost, and an abnormally high amount of platelets enter the circulation. In time, the rate of thrombopoiesis slows to reestablish a more normal platelet level.

Clinical Manifestations

Signs and symptoms of bleeding disorders vary depending on the type of defect. A careful history and physical examination can be very useful in determining the source of the hemostatic defect. Abnormalities of the vascular system give rise to local bleeding, usually into the skin. Because platelets are primarily responsible for stopping bleeding from small vessels, patients with platelet defects develop petechiae, often in clusters; these are seen on the skin and mucous membranes but also occur throughout the body. Bleeding from platelet disorders can be severe. Unless the platelet disorder is severe, bleeding can often be stopped promptly when local pressure is applied; it does not typically recur when the pressure is released.

In contrast, coagulation factor defects do not tend to cause superficial bleeding, because the primary hemostatic mechanisms are still intact. Instead, bleeding occurs deeper within the body (eg, subcutaneous or intramuscular hematomas, hemorrhage into joint spaces). External bleeding diminishes very slowly when local pressure is applied; it often recurs several hours after pressure is removed. For example, severe bleeding may start several hours after a tooth extraction. Risk factors for bleeding are provided in Chart 33-7.

Medical Management

Management varies based on the underlying cause of the bleeding disorder. If bleeding is significant, transfusions of blood products are indicated. The specific blood product used is determined by the underlying defect. In specific situations in which fibrinolysis is excessive, hemostatic agents such as aminocaproic acid (Amicar) can be used to inhibit this process. This agent must be used with caution, because excessive inhibition of fibrinolysis can result in thrombosis.

Nursing Management

Patients who have bleeding disorders or who have the potential for development of such disorders as a result of disease or therapeutic agents must be taught to observe themselves carefully and frequently for bleeding. They need to understand the importance of avoiding activities that increase the risk of bleeding, such as contact sports. The skin is observed for petechiae and ecchymoses (bruises) and the nose and gums for bleeding. Hospitalized patients may be monitored for bleeding by testing all drainage and excreta (feces, urine, emesis, and gastric drainage) for occult as well as obvious blood. Outpatients are often given fecal occult blood screening cards to detect occult blood in stools.

PRIMARY THROMBOCYTHEMIA

Primary thrombocythemia (also called essential thrombocythemia) is a stem cell disorder within the bone marrow. A marked increase in platelet production occurs, with the platelet count consistently greater than 600,000/mm³. Platelet size may be abnormal, but platelet survival is typically normal. Occasionally, the platelet increase is accompanied by an increase in RBCs or WBCs or both; however, these cells are not increased to the extent that they are in polycythemia vera, CML, or myelofibrosis. Although the exact cause is unknown, primary thrombocythemia is similar to other myeloproliferative disorders, particularly polycythemia vera. Unlike the other myeloproliferative disorders, however, it rarely evolves into acute leukemia.

Clinical Manifestations

Many patients with primary thrombocythemia are asymptomatic; the illness is diagnosed as the result of finding an elevated platelet count on a CBC. Symptoms, when they do occur, result primarily from hemorrhage or vasoocclusion in the microvasculature. Symptoms may occur more when the platelet count exceeds 1 million/mm³. However, symptoms do not always correlate with the extent to which the platelet count is elevated. Thrombosis is common and can be either arterial or venous; major thromboses occur in 15% to 40% of these patients (Jantunen et al., 2001). Because these platelets can be dysfunctional, minor or major hemorrhage can also occur. Bleeding from the mucous membranes of the nose and mouth is common, and significant gastrointestinal bleeding is also possible. Bleeding typically does not occur until the platelet count exceeds 1 million/mm³.

Vasoocclusive manifestations are most frequently seen in the form of erythromelalgia. The toxic effects of platelet substances include painful burning, warmth, and redness in a localized distal area of the extremities. Neurologic manifestations may also be seen, such as numbness, tingling, and visual disturbance; these occlusive manifestations can progress to stroke and seizure and, less commonly, to myocardial infarction. The spleen may be enlarged, but usually not to a significant extent.

Assessment and Diagnostic Findings

The diagnosis of primary thrombocythemia is made by ruling out other potential disorders. Iron deficiency should be excluded, because a reactive increase in the platelet count often accompanies this deficiency. The myeloproliferative disorders (CML, polycythemia vera) should also be excluded. Examination of the CBC shows markedly abnormal platelets. Analysis of the bone marrow (by aspiration and biopsy) shows a marked increase in megakaryocytes (platelet precursors) and is useful in excluding CML as a possible cause for the elevated platelet count. The disease, which affects men and women equally, tends to occur in late middle age. The median survival time exceeds 10 years.

No data reliably predict the development of complications. Risk factors for the development of thrombotic complications are
age greater than 65 years, prior thrombotic events, and long duration of thrombocytosis. Major bleeding tends to occur when the platelet count is very high.

**Medical Management**

The management of primary thrombocythemia is highly controversial. The risk of significant thrombotic or hemorrhagic complications may not be increased until the platelet count exceeds 1 million/mm³ (Briere & Guilmin, 2001). A careful assessment of other risk factors, such as history of peripheral vascular disease, history of tobacco use, atherosclerosis, and prior thrombotic events, should be used in making the decision as to when to initiate therapy. In younger patients with no risk factors, low-dose aspirin therapy may be sufficient to prevent thrombotic complications; however, the use of aspirin can increase the risk for hemorrhagic complications and may be considered a contraindication in patients with a history of gastrointestinal bleeding. The neurologic symptoms (eg, headache and erythromelalgia) and visual symptoms of primary thrombocytopenia can be relieved by low-dose aspirin.

More aggressive measures may be required in older patients and those with concurrent risk factors. Hydroxyurea (eg, Hydrea), a chemotherapeutic medication, is effective in lowering the platelet count. It is taken orally and causes minimal side effects other than dose-related leukopenia. However, its potential for leukogenesis is in question. The medication anagrelide (Agrylin) is more specific in lowering the platelet count than is hydroxyurea, but it has more side effects. Severe headaches cause many patients to stop taking the medication. Tachycardia and chest pain may also occur, and anagrelide is contraindicated in patients with concurrent cardiac problems. Interferon-alfa-2b (eg, Intron-A) has been shown to lower platelet counts by an unknown mechanism. The medication is administered subcutaneously at varying frequency, commonly three times per week. Significant side effects, such as fatigue, weakness, memory defects, dizziness, anemia, and liver dysfunction, limit its usefulness.

Rarely, the occlusive symptoms are so great that the platelet count must be reduced immediately. Platelet pheresis (see later discussion) can reduce the amount of circulating platelets, but the extent by which symptoms and complications (eg, thromboses) are reduced remains unclear.

**Nursing Management**

Patients with primary thrombocythemia need to be instructed about the accompanying risks of hemorrhage and thrombosis. Patients should be informed about signs and symptoms of thrombosis, particularly the neurologic manifestations, such as visual changes, numbness, tingling, and weakness. Risk factors for thrombosis should be assessed, and measures to diminish risk factors (particularly cessation of tobacco use) should be encouraged. Patients receiving aspirin therapy should be informed about the increased risk for bleeding. Patients who are at risk for bleeding should be instructed about medications that can alter platelet function, such as aspirin, NSAIDs, and alcohol. Patients receiving interferon therapy should be taught to self-administer the medication and manage side effects.

**SECONDARY THROMBOCYTOSIS**

Increased platelet production is the primary mechanism of secondary, or reactive, thrombocytosis. The platelet count is above normal, but, in contrast to primary thrombocythemia, an increase above 1 million/mm³ is rare. Platelet function is normal; the platelet survival time is normal or decreased. Symptoms associated with hemorrhage or thrombosis are rare. Many disorders can cause a reactive increase in platelets, including chronic inflammatory disorders, iron deficiency, malignant disease, acute hemorrhage, and splenectomy (see previous discussion of primary thrombocythemia). Treatment is aimed at the underlying disorder. With successful management, the platelet count usually returns to normal.

**THROMBOCYTOPENIA**

Thrombocytopenia (low platelet level) can result from various factors: decreased production of platelets within the bone marrow, increased destruction of platelets, or increased consumption of platelets. Causes and treatments are summarized in Table 33-5.

**Clinical Manifestations**

Bleeding and petechiae usually do not occur with platelet counts greater than 50,000/mm³, although excessive bleeding can follow surgery or other trauma. When the platelet count drops below

</table>
20,000/mm³, petechiae can appear, along with nose and gingival bleeding, excessive menstrual bleeding, and excessive bleeding after surgery or dental extractions. When the platelet count is less than 5000/mm³, spontaneous, potentially fatal central nervous system bleeding, excessive menstrual bleeding, and excessive bleeding after gastrointestinal hemorrhage can occur. If the platelets are dysfunctional due to disease (eg, MDS) or medications (eg, aspirin), the risk of bleeding may be much greater even when the actual platelet count is not significantly reduced.

**Assessment and Diagnostic Findings**

A platelet deficiency that results from decreased production (eg, leukemia, MDS) can usually be diagnosed by examining the bone marrow via aspiration and biopsy. When platelet destruction is the cause of thrombocytopenia, the marrow shows increased megakaryocytes (the cells from which the platelets originate) and normal or even increased platelet production as the body attempts to compensate for the decreased platelets in circulation. Another cause of thrombocytopenia is sequestration. Approximately one third of the circulating platelets are within the spleen, and a greatly enlarged spleen results in increased sequestration of platelets.

**Medical Management**

The management for secondary thrombocytopenia is usually treatment of the underlying disease. If platelet production is impaired, platelet transfusions may raise the platelet count and stop bleeding or prevent spontaneous hemorrhage. If excessive platelet destruction occurs, transfused platelets will also be destroyed, and the platelet count will not rise. The most common cause of excessive platelet destruction is ITP (see the following discussion). In some instances splenectomy can be a useful therapeutic intervention, but often it is not a therapeutic option, for example in patients in whom the enlarged spleen is due to portal hypertension related to excessive alcohol consumption.

**Nursing Management**

The interventions for a patient with thrombocytopenia are delineated in Chart 33-10.

**IDIOPATHIC THROMBOCYTOPENIC PURPURA (ITP)**

ITP is a disease that affects people of all ages, but it is more common among children and young women. There are two forms of ITP: acute and chronic. The acute form, which occurs predominantly in children, often appears 1 to 6 weeks after a viral illness. This form is self-limited; remission often occurs spontaneously within 6 months. Occasionally, corticosteroids are needed for a brief time. Chronic ITP is often diagnosed by exclusion of other causes of thrombocytopenia.

**Pathophysiology**

Although the precise cause remains unknown, viral infections sometimes precede ITP in children. Occasionally medications such as sulfa drugs can induce ITP. Other conditions, such as systemic lupus erythematosus (SLE) or pregnancy, can also induce ITP. Anti-platelet autoantibodies that bind to the patient’s platelets are found in the blood of patients with ITP. When the platelets are bound by the antibodies, the RES or tissue macrophage system ingests the platelets, destroying them. The body attempts to compensate for this destruction by increasing platelet production within the marrow.

**Clinical Manifestations**

Many patients have no symptoms, and the low platelet count (often less than 20,000/mm³, and less than 5000/mm³ is not uncommon) is an incidental finding. Common physical manifestations are easy bruising, heavy menses, and petechiae on the extremities or trunk. Patients with simple bruising or petechiae (“dry purpura”) tend to have fewer complications from bleeding than those with bleeding from mucosal surfaces, such as the gastrointestinal tract (including the mouth) and pulmonary system (eg, hemoptysis), which is termed “wet purpura.” Patients with wet purpura have a greater risk for intracranial bleeding than do those with dry purpura. Despite low platelet counts, the platelets are young and very functional. They adhere to endothelial surfaces and to one another, so spontaneous bleeding does not always occur.

**Assessment and Diagnostic Findings**

Patients may have an isolated decrease in platelets (less than 20,000/mm³ is common), but they may also have an increase in megakaryocytes (platelet precursors) within the marrow, as detected on bone marrow aspirate.

**Medical Management**

The primary goal of treatment is a safe platelet count. Because the risk of bleeding typically does not increase until the platelet count is lower than 10,000/mm³, patients whose counts exceed 30,000 to 50,000/mm³ may be carefully observed without additional intervention. However, if the count is lower than 20,000/mm³, or if bleeding occurs, the goal is to improve the patient’s platelet count, rather than to cure the disease. Treatment for ITP usually requires several approaches. If the patient is taking a medication that is known to cause ITP (eg, quinine, sulfon containing medications), that medication must be stopped immediately. The mainstay of short-term therapy is the use of immunosuppressive agents. The immunosuppressants block the binding receptors on macrophages so that the platelets are not destroyed. Prednisone is the agent typically used (at a dose of 1 mg/kg), and it is effective in about 75% of patients. Cyclophosphamide (eg, Cytoxan) and azathioprine (Imuran) can also be used, and dexamethasone (eg, Decadron) may be effective. Platelet counts rise within a few days after institution of corticosteroid therapy; this effect takes longer with azathioprine. Because of the associated side effects, patients cannot take high doses of corticosteroids indefinitely. It is not unusual for the platelet count to drop once the corticosteroid dose is tapered. Some patients can be successfully maintained on low doses of prednisone (eg, 2.5 to 10 mg every other day).

Intravenous gamma globulin (IVIG) is also commonly used to treat ITP. It is effective in binding the receptors on the macrophages; however, high doses (1 g/kg for 2 days) are required, and the drug is very expensive. Splenectomy is an alternative treatment but results in a normal platelet count only 50% of the time; however, many patients can maintain a “safe” platelet count of more than 30,000/mm³ after removal of the spleen. Even those who do respond to splenectomy may have recurrences of severe thrombocytopenia months or years later. Patients who
have splenectomy are permanently at risk for sepsis; these patients should receive Pneumovax, Haemophilus influenzae B, and meningococcal vaccines, preferably 2 to 3 weeks before the splenectomy is preferred. Pneumovax vaccine should be repeated at 5- to 10-year intervals.

Other options for management include use of the chemotherapy agent vincristine (Oncovir). Vincristine appears to work by blocking the receptors on the macrophages and therefore inhibiting platelet destruction; it may also stimulate thrombopoiesis. Some data support the efficacy of certain monoclonal antibodies (eg, rituximab) in increasing platelet counts, but more research is needed (Stasi, Pagano, Stipa, & Amadori, 2001; Saleh et al., 2000).

Another approach to the management of chronic ITP involves the use of anti-D (eg, WinRho) in patients who are Rh(D)-positive. The actual mechanism of action is unknown. One theory is that the anti-D binds to the patient’s RBCs, which are in turn destroyed by the body’s macrophages. While the macrophages destroy the anti-D/RBC complex, they are not able to destroy platelets. Anti-D produces a transient decreased hematocrit and increased platelet count in many, but not all, patients with ITP. Anti-D appears to be most effective in children with ITP and least effective in patients who have undergone splenectomy.

Despite the extremely low platelet count, platelet transfusions are usually avoided. Transfusions tend to be ineffective because the patient’s anti-platelet antibodies bind with the transfused platelets, causing them to be destroyed. Platelet counts can actually drop after platelet transfusion. Occasionally, transfusion of platelets may protect against catastrophic bleeding in patients with severe wet purpura. Epsilon-aminocaproic acid (EACA; Amicar) may be useful for patients with significant mucosal bleeding refractory to other treatments.

Nursing Management

Nursing care for these patients should include an assessment of the patient’s life style to determine the risk of bleeding from activity. A careful medication history should also be obtained, including use of over-the-counter medications, herbs, and nutritional supplements. The nurse must be alert for sulf-a-containing medications and medications that alter platelet function (eg, medications that contain aspirin or other NSAIDs). The nurse should assess for any history of recent viral illness and reports of headache or visual disturbances (which could be initial symptoms of intracranial bleeding). Patients who are admitted to the hospital with wet purpura and low platelet counts should have a neurologic assessment incorporated into their routine vital sign measurements. No intramuscular injections or rectal medications should be administered, and rectal temperature measurements should not be performed, because they can stimulate bleeding.

Patient teaching should address signs of exacerbation of disease (petechiae, ecchymoses); how to contact appropriate health care personnel; the name and type of medication inducing ITP (if appropriate); current medical treatment (medications, tapering schedule if relevant, side effects); and the frequency of monitoring the platelet count. Patients should be instructed to avoid all agents that interfere with platelet function. The patient should avoid constipation, the Valsalva maneuver (eg, straining at stool), and flossing of the teeth. Electric razors should be used for shaving, and soft-bristled toothbrushes should replace stiff-bristled ones. Patients should also be counseled to refrain from vigorous sexual intercourse when the platelet count is less than 10,000/mm³. Patients who are receiving chronic corticosteroids are at risk for complications including osteoporosis, proximal muscle wasting, cataract formation, and dental caries (see Chart 33-4). Bone mineral density should be monitored, and these patients may benefit from calcium and vitamin D supplementation and bisphosphonate therapy to prevent significant bone disease.

PLATELET DEFECTS

Quantitative platelet defects are relatively common (thrombocytopenia), but qualitative defects can also occur. With qualitative defects, the number of platelets may be normal, but the platelets do not function normally. Platelet function is most commonly evaluated by the bleeding time; however, this test is a crude measurement at best.

An important functional platelet disorder is that induced by aspirin. Even small amounts of aspirin reduce normal platelet aggregation, and the prolonged bleeding time lasts for several days after aspirin ingestion. Although this does not cause bleeding in most people, patients with a coagulation disorder (eg, hemophilia) or thrombocytopenia can have significant bleeding after taking aspirin, particularly if invasive procedures or trauma has occurred.

NSAIDs can also inhibit platelet function, but the effect is not as prolonged as with aspirin (about 5 days versus 7 to 10 days). Other causes of platelet dysfunction include end-stage renal disease, possibly from metabolic products affecting platelet function; MDS; multiple myeloma (due to abnormal protein interfering with platelet function); cardiopulmonary bypass; and other medications and substances (Chart 33-13).

Clinical Manifestations

Bleeding may be mild or severe. Its extent is not necessarily correlated with the platelet count or with tests that measure coagulation (prothrombin time [PT], partial thromboplastin time [PTT]). Ecchymoses are common, particularly on the extremities. Patients with platelet dysfunction may be at risk for significant bleeding after trauma or invasive procedures (eg, biopsy, dental extraction).

Medical Management

If the platelet dysfunction is caused by medication, use of the offending medication should be stopped, if possible, particularly when bleeding occurs. If platelet dysfunction is marked, bleeding can often be prevented by transfusion of normal platelets before invasive procedures. Amniocaproic acid (EACA; Amicar) may be required to prevent significant bleeding after such procedures.

Nursing Management

Patients with significant platelet dysfunction need to be instructed to avoid agents that can diminish platelet function, such as certain over-the-counter medications, herbs, nutritional supplements, and alcohol. They also need to be assisted to serve as their own advocates and to inform their health care providers (including dentists) of the underlying condition before any invasive procedure is performed, so that appropriate steps can be initiated to diminish the risk of bleeding. Bleeding precautions should be initiated as appropriate (see Chart 33-10).

HEMOPHILIA

Two inherited bleeding disorders—hemophilia A and hemophilia B—are clinically indistinguishable, although they can be distinguished by laboratory tests. Hemophilia A is caused by a
Mophilia occurs in all ethnic groups. Severe trauma (eg, a high-school football injury) or surgery. He-mophilia may not be diagnosed until they experience childhood, usually in the toddler age group. However, patients almost always asymptomatic. The disease is recognized in early most all affected people are males; females can be carriers but are relatively rare disease; hemophilia A, which occurs in 1 of every 10,000 births, is three times more common than hemophilia B. Both types of hemophilia are inherited as X-linked traits, so affect that causes deficient or defective factor IX. Hemophilia is a relatively rare disease; hemophilia A, which occurs in 1 of every 10,000 births, is three times more common than hemophilia B. Both types of hemophilia are inherited as X-linked traits, so almost all affected people are males; females can be carriers but are almost always asymptomatic. The disease is recognized in early childhood, usually in the toddler age group. However, patients with mild hemophilia may not be diagnosed until they experience severe trauma (eg, a high-school football injury) or surgery. Hemophilia occurs in all ethnic groups.

Clinical Manifestations

The disease, which can be severe, is manifested by hemorrhages into various parts of the body. Hemorrhage can occur even after minimal trauma. The frequency and severity of the bleeding depend on the degree of factor deficiency as well as the intensity of the precipitating trauma. For example, patients who have a mild factor VIII deficiency (ie, 6% to 50% of normal levels) rarely develop hemorrhage spontaneously; hemorrhage tends to occur secondary to trauma. In contrast, spontaneous hemorrhages, particularly hemarthroses and hematomas, can frequently occur in patients with severe factor VIII deficiency (ie, less than 1% of normal levels). These patients require frequent factor replacement therapy.

About 75% of all bleeding in patients with hemophilia occurs into joints. The most commonly affected joints are the knees, elbows, ankles, shoulders, wrists, and hips. Patients often note pain in a joint before they are aware of swelling and limitation of motion. Recurrent joint hemorrhages can result in damage so severe that chronic pain or ankylosis (fixation) of the joint occurs. Many patients with severe factor deficiency are crippled by the joint damage before they become adults. Hematomas can be superficial or deep hemorrhages into muscle or subcutaneous tissue. With severe factor deficiency, they can occur without known trauma and progressively extend in all directions. When the hematomas occur within muscle, particularly in the extremities, peripheral nerves can be compressed. Over time, this compression results in decreased sensation, weakness, and atrophy of the area involved. Spontaneous hematuria and gastrointestinal bleeding can occur. Bleeding is also common in other mucous membranes, such as the nasal passages. The most dangerous site of hemorrhage is in the head (intracranial or extracranial). Any head trauma requires prompt evaluation and treatment. Surgical procedures typically result in excessive bleeding at the surgical site. Because clot formation is poor, wound healing is also poor. Such bleeding is most commonly associated with dental extraction.

Medical Management

In the past, the only treatment for hemophilia was infusion of fresh frozen plasma, which had to be administered in such large quantities that patients experienced fluid volume overload. Now factor VIII and factor IX concentrates are available to all blood banks. Recombinant forms of these factors have been made available and may diminish the use of factor concentrates. Patients are given concentrates when they are actively bleeding or as a preventive measure before traumatic procedures (eg, lumbar puncture, dental extraction, surgery). The patient and family are taught how to administer the concentrate intravenously at home at the first sign of bleeding. It is crucial to initiate treatment as soon as possible so that bleeding complications can be avoided. A few patients eventually develop antibodies to the concentrates, so their factor levels cannot be increased. Treatment of this problem is extremely difficult and often unsuccessful.

Aminocaproic acid (EACA; Amicar) is a fibrinolytic enzyme inhibitor that can slow the dissolution of blood clots that do form; it is very effective as an adjunctive measure after oral surgery. It is also useful in treating mucosal bleeding. Another agent, desmopressin (eg, DDAVP), induces a transient rise in factor VIII levels; the mechanism for this response is unknown. In patients with mild forms of hemophilia A, desmopressin is extremely useful, significantly reducing the amount of blood products required. However, desmopressin is not effective in patients with severe factor VIII deficiency.

Nursing Management

Most patients with hemophilia are diagnosed as children. They often require assistance in coping with the condition because it is chronic, places restrictions on their lives, and is an inherited disorder that can be passed to future generations. From childhood, patients are helped to accept themselves and the disease and to identify the positive aspects of their lives. They are encouraged to be
self-sufficient and to maintain independence by preventing unnecessary trauma that can cause acute bleeding episodes and temporarily interfere with normal activities. As they work through their feelings about the condition and progress to accepting it, they can assume more and more responsibility for maintaining optimal health.

Patients with mild factor deficiency may not be diagnosed until adulthood if they do not experience significant trauma or surgery as children. These patients need extensive teaching about activity restrictions and self-care measures to diminish the chance of hemorrhage and complications of bleeding. The nurse should emphasize safety at home and in the workplace.

Patients with hemophilia are instructed to avoid any agents that interfere with platelet aggregation, such as aspirin, NSAIDs, herbs, nutritional supplements, and alcohol. This restriction applies to over-the-counter medications such as cold remedies. Dental hygiene is very important as a preventive measure because dental extractions are so hazardous. Applying pressure may be sufficient to control bleeding resulting from minor trauma if the factor deficiency is not severe. Nasal packing should be avoided, because bleeding frequently resumes when the packing is removed. Splints and other orthopedic devices may be useful in patients with joint or muscle hemorrhages. All injections should be avoided; invasive procedures (eg, endoscopy, lumbar puncture) should be minimized or performed after administration of appropriate factor replacement. Patients with hemophilia should be encouraged to carry or wear medical identification.

During hemorrhagic episodes, the extent of bleeding must be assessed carefully. Patients who are at risk for significant compromise (eg, bleeding into the respiratory tract or brain) warrant close observation and systematic assessment for emergent complications (eg, respiratory distress, altered level of consciousness). If the patient has had recent surgery, the nurse frequently and carefully assesses the surgical site for bleeding. Frequent vital sign monitoring is needed until the nurse is certain that there is no excessive postoperative bleeding.

Analgesics are commonly required to alleviate the pain associated with hematomas and hemorrhage into joints. Many patients report that warm baths promote relaxation, improve mobility, and lessen pain. However, during bleeding episodes, heat, which can accentuate bleeding, is avoided; applications of cold are used instead.

Although recent technology (ie, the formulation of heat-solvent or detergent-treated factor concentrates) has rendered factor VIII and IX preparations free from viruses such as HIV and hepatitis, many patients have already been exposed to these infections. These patients and their families may need assistance in coping with the diagnosis and the consequences of these infections.

Between 15% and 50% of patients with hemophilia A and between 1% and 3% of patients with hemophilia B develop antibodies (inhibitors) to factor concentrates, complicating factor replacement management (Lusher, 2000; White, Greenwood, Escobar, & Frelinger, 2000). These patients may require plasmapheresis or concurrent immunosuppressive therapy, particularly in the setting of significant bleeding. Patients with severe factor deficiency should be screened for antibodies, particularly before major surgery.

VON WILLEBRAND’S DISEASE

Von Willebrand’s disease, a common bleeding disorder affecting males and females equally, is usually inherited as a dominant trait. The disease is caused by a deficiency of von Willebrand factor (vWF), which is necessary for factor VIII activity. vWF is also necessary for platelet adhesion at the site of vascular injury. Although synthesis of factor VIII is normal, its half-life is shortened; therefore, factor VIII levels commonly are mildly low (15% to 50% of normal).

Clinical Manifestations

Patients commonly have nosebleeds, excessively heavy menses, bleeding from cuts, and postoperative bleeding, although they do not suffer from massive soft tissue or joint hemorrhages. As the laboratory values fluctuate, so does the bleeding. For example, a careful history of prior bleeding may show little problem with postoperative bleeding on one occasion but significant bleeding from a dental extraction at another time.

Assessment and Diagnostic Findings

Laboratory test results show a normal platelet count but prolonged bleeding time and slightly prolonged PTT. These defects are not static, and laboratory test results can vary widely within the same patient over time.

Medical Management

Both the factor deficiency and the platelet impairment can be corrected by administration of cryoprecipitate, which contains factor VIII, fibrinogen, and factor XIII (or fresh frozen plasma, if cryoprecipitate is unavailable). Replacement continues for several days to ensure correction of the factor VIII deficiency; up to 7 to 10 days of treatment may be necessary after major surgery. Desmopressin (DDAVP), a synthetic vasopressin analog, can be used to prevent bleeding associated with dental or surgical procedures or to manage mild bleeding after surgery. Desmopressin provides a transient increase in factor VIII coagulant activity and may also correct the bleeding time. It can be administered as an intravenous infusion or intranasally. With major surgery or invasive procedures, both desmopressin and cryoprecipitate may be needed to prevent hemorrhage.

Acquired Coagulation Disorders

LIVER DISEASE

With the exception of factor VIII, most blood coagulation factors are synthesized in the liver. Therefore, hepatic dysfunction (due to cirrhosis, tumor, or hepatitis; see Chap. 39) can result in diminished amounts of the factors needed to maintain coagulation and hemostasis. Prolongation of the PT, unless it is caused by vitamin K deficiency, may indicate severe hepatic dysfunction. Although minor bleeding is common (eg, ecchymoses), these patients are also at risk for significant bleeding, related especially to trauma or surgery. Transfusion of fresh frozen plasma may be required to replace clotting factors and to prevent or stop bleeding. Patients may also have life-threatening hemorrhage from peptic ulcers or esophageal varices. In these cases, replacement with fresh frozen plasma, PRBCs, and platelets is usually required.

VITAMIN K DEFICIENCY

The synthesis of many coagulation factors depends on vitamin K. Vitamin K deficiency is typical in malnourished patients, and some antibiotics decrease the intestinal flora that produce vitamin K, depleting vitamin K stores. Administration of vitamin K (phyton-
DIC is not a disease but a sign of an underlying condition. DIC may be triggered by sepsis, trauma, cancer, shock, abruptio placentae, toxins, or allergic reactions (Chart 33-14). It is potentially life-threatening.

**Pathophysiology**

In DIC, the normal hemostatic mechanisms are altered so that a massive amount of tiny clots forms in the microcirculation. Initially, the coagulation time is normal. However, as the platelets and clotting factors are consumed to form the microthrombi, coagulation fails. Thus, the paradoxical result of excessive clotting is bleeding. The clinical manifestations of DIC are reflected in the organs, which are affected either by excessive clot formation (with resultant ischemia to all or part of the organ) or by bleeding. The bleeding is characterized by low platelet and fibrinogen levels; prolonged PT, PTT, and thrombin time; and elevated fibrin degradation products (D-dimers) (Table 33-6).

The mortality rate can exceed 80% of patients who develop DIC. Identification of patients who are at risk for DIC and recognition of the early clinical manifestations of this syndrome can result in earlier medical intervention, which may improve the prognosis. However, the primary prognostic factor is the ability to treat the underlying condition that precipitated DIC.

**Clinical Manifestations**

Patients with DIC may bleed from mucous membranes, venipuncture sites, and the gastrointestinal and urinary tracts. The bleeding can range from minimal occult internal bleeding to profuse hemorrhage from all orifices. Patients may also develop organ dysfunction, such as renal failure and pulmonary and multifocal central nervous system infarctions as a result of microthromboses, macrothromboses, or hemorrhages.

During the initial process of DIC, the patient may have no new symptoms, the only manifestation being a progressive decrease in the platelet count. As the thrombosis becomes more extensive, the patient exhibits signs and symptoms of thrombosis in the organs involved. Then, as the clotting factors and platelets are consumed to form these thrombi, bleeding occurs. Initially the bleeding is subtle, but it can develop into frank hemorrhage. Signs and symptoms depend on the organs involved and are listed in Table 33-7.

**Medical Management**

The most important management issue is treating the underlying cause of the DIC. Until the cause is controlled, the mechanism for DIC will persist. A second goal is to correct the secondary effects of tissue ischemia by improving oxygenation, replacing fluids, correcting electrolyte imbalances, and administering vasopressor medications. If serious hemorrhage occurs, the depleted coagulation factors and platelets may be replaced to reestablish the potential for normal hemostasis and thereby diminish bleeding. Cryoprecipitate is given to replace fibrinogen and factors V and VII; fresh frozen plasma is administered to replace other coagulation factors.

A controversial method to interrupt the thrombosis process is the use of heparin infusion. Heparin may inhibit the formation of microthrombi and thus permit perfusion of the organs (skin, kidneys, or brain) to resume. Heparin is typically reserved for the patient in whom thrombotic manifestations predominate or in whom extensive blood component replacement fails to halt the hemorrhage or increase fibrinogen and other clotting levels. When heparin is administered, bleeding may actually worsen initially until the thrombotic process is interrupted. Consumed platelets and clotting factors need to be replaced. The effectiveness of heparin can best be determined by observing for normalization of the plasma fibrinogen concentration and diminishing signs of bleeding.

**NURSING PROCESS:**

**THE PATIENT WITH DISSEMINATED INTRAVASCULAR COAGULATION (DIC)**

**Assessment**

Nurses need to be aware of patients who are at risk for DIC. Sepsis and acute promyelocytic leukemia are the most common causes of DIC. Patients need to be assessed thoroughly and frequently for signs and symptoms of thrombi and bleeding and monitored for any progression of these signs (see Table 33-7).

**Diagnosis**

**NURSING DIAGNOSES**

Based on the assessment data, major nursing diagnoses for the patient with DIC may include the following:

- Risk for deficient fluid volume related to bleeding
- Risk for impaired skin integrity related to ischemia or bleeding
- Potential for excess fluid volume related to excessive blood/ factor component replacement
- Ineffective tissue perfusion related to microthrombi
- Anxiety and fear of the unknown and possible death

**Chart 33-14**

**Risk Factors for Disseminated Intravascular Coagulation (DIC)**

- Sepsis
- Obstetric complications
- Acute hemolysis (eg, transfusion reaction)
- Trauma
- Shock
- Cancer (especially prostate cancer and acute promyelocytic leukemia)
- Allergic reactions
Collaborative problems include the clinical conditions that precipitated the DIC. Based on the assessment data, potential complications may include:

- Renal failure
- Gangrene
- Pulmonary embolism or hemorrhage
- Altered level of consciousness
- Acute respiratory distress syndrome
- Stroke

Planning and Goals

Major patient goals include maintenance of hemodynamic status, maintenance of intact skin and oral mucosa, maintenance of fluid balance, maintenance of tissue perfusion, enhanced coping, and absence of complications (see Plan of Nursing Care).

Nursing Interventions

See Plan of Nursing Care: The Patient with Disseminated Intravascular Coagulation.

Monitoring and Managing Potential Complications

Despite aggressive measures, the lack of renal perfusion may result in acute renal failure, sometimes necessitating dialysis. Placement of a large-bore dialysis catheter is extremely hazardous in this patient population and should be accompanied by adequate platelet and plasma transfusions.

</tr>
</tbody>
</table>

*Note: Signs of microvascular thrombosis are the result of an inappropriate activation of the coagulation system, causing thrombotic occlusion of small vessels within all body organs. As the clotting factors and platelets are consumed, signs of microvascular bleeding appear. This bleeding can quickly extend into frank hemorrhage. Treatment must be aimed at the disorder underlying the DIC; otherwise, the stimulus for the syndrome will persist.

*heme⁺, positive for hemoglobin
# Plan of Nursing Care

## The Patient With Disseminated Intravascular Coagulation (DIC)

### Nursing Interventions | Rationale | Expected Outcomes
--- | --- | ---
**Nursing Diagnosis:** Potential for fluid volume deficit related to bleeding  
**Goals:** Hemodynamic status maintained  
Urine output ≥ 30 mL/hr

1. Avoid procedures/activities that can increase intracranial pressure (e.g., coughing, straining to have a bowel movement).  
   - Level of consciousness (LOC) stable
   - CVP 5–12 cm H2O, systolic BP ≥ 70 mm Hg
   - Urine output ≥ 30 mL/hour
   - Decreased bleeding
   - Decreased oozing
   - Decreased ecchymoses
   - Amenorrhea
   - Absence of oral and bronchial bleeding
   - Oral mucosa clean, moist, intact
   - Absence of bleeding

2. Monitor vital signs closely, including neurologic checks:
   - a. Monitor hemodynamics  
   - b. Monitor abdominal girth  
   - c. Monitor urine output  
   - b. Identifies signs of hemorrhage/shock quickly.

3. Avoid medications that interfere with platelet function if possible (e.g., ASA, NSAIDs, beta-lactam antibiotics).  
   - a. Provides accurate, objective assessment of extent of bleeding.

4. Avoid rectal probes, rectal medications.  
   - b. Identifies presence of or quantifies extent of bleeding.

5. Avoid IM injections.  
   - c. Quantifies extent of bleeding.

6. Monitor amount of external bleeding carefully
   - a. Monitor number of dressings, % of dressing saturated; time to saturate a dressing is more objective than “dressing saturated a moderate amount.”  
   - b. Monitor suction output, all excreta  
   - c. Monitor pad counts in menstruating females.  
   - d. Females may receive progesterone to prevent menses.  
   - d. Decreases chance for gynecologic source of hemorrhage.

7. Use low pressure with any suctioning needed.  
   - 7. Prevents excessive trauma that could cause bleeding.

8. Administer oral hygiene carefully.
   - a. Avoid lemon-glycerine swabs, hydrogen peroxide, commercial mouthwashes.  
   - b. Use sponge-tipped swabs, salt/baking soda (bicarbonate of soda) mouth rinses.  
   - b. Prevents excessive trauma that could cause bleeding.
   - Glycerin and alcohol (in commercial mouthwashes) will dry mucosa, increasing risk for bleeding.

9. Avoid dislodging any clots, including those around IV sites and injection sites.  
   - 9. Prevents excessive bleeding at sites.

### Nursing Diagnosis: Potential for impaired skin integrity secondary to ischemia or bleeding  
**Goals:** Skin integrity remains intact; oral mucosa remains intact

1. Assess skin, with particular attention to bony prominences, skin folds.  
   - Skin integrity remains intact; skin is warm, and of normal color
   - Oral mucosa is intact, pink, moist, without bleeding

2. Reposition carefully; use pressure-reducing mattress.  
2–4. Meticulous skin care and use of measures to prevent pressure on bony prominences decrease the risk of skin trauma.

3. Perform careful skin care every 2 hr, emphasizing dependent areas, all bony prominences, perineum.  

4. Use lamb’s wool between digits, around ears, as needed.

5. Use prolonged pressure after injection or procedure when such measures must be performed (at least 5 min)

6. Administer oral hygiene carefully (see above).

5. Initial platelet plug is very unstable and easily dislodged, which can lead to increased bleeding.

6. Mettuculous care to decreased trauma, bleeding, and risk of infection.

(continued)

**Evaluation**

See the Plan of Nursing Care for evaluation and expected outcomes for the patient with DIC.

**THROMBOTIC DISORDERS**

As in many bleeding disorders, several conditions can alter the balance within the normal hemostasis process and cause excessive thrombosis. Abnormalities that predispose a person to thrombotic events include decreased clotting inhibitors within the circulation (which enhances coagulation), altered hepatic function (which may decrease production of clotting factors or clearance of activated coagulation factors), lack of fibrinolytic enzymes, and tortuous vessels (which promote platelet aggregation). Thrombosis can be caused by more than one predisposing factor. Several conditions can result from thrombosis, such as myocardial infarction (see Chap. 28), cerebral vascular accident...
(CVA, brain attack, or stroke; see Chap. 62), and peripheral arterial occlusion (see Chap. 31). Several inherited or acquired deficiency conditions, including hyperhomocystinemia, antithrombin III (AT III) deficiency, Protein C deficiency, activated Protein C (APC) resistance, factor V Leiden, and Protein S deficiency can predispose a patient to repeated episodes of thrombosis; they are referred to as hypercoagulable states or thrombophilia. Table 33-8 delineates these disorders, their abnormal laboratory values, and the need for family testing.

Thrombosis requires anticoagulation therapy. The duration of therapy varies with the location and extent of the thrombosis, precipitating events (eg, trauma, immobilization), and concurrent risk factors (eg, use of oral contraceptives, tortuous blood vessels, history of thrombotic events).

HYPERHOMOCYSTINEMIA

Increased plasma levels of homocystine are a significant risk factor not only for venous thrombosis (eg, deep venous thrombosis [DVT], pulmonary embolism) but also for arterial thrombosis (eg, stroke, myocardial infarction). This disorder can be hereditary, or it can result from a nutritional deficiency of folic acid and, to a lesser extent, of vitamin B₁₂ and B₉, because these vitamins are cofactors in homocystine metabolism. For unknown reasons, people who are elderly, have renal failure, or smoke tobacco may also have elevated levels of homocystine in the absence of nutritional deficiencies of these vitamins. Although a simple fasting measurement of plasma homocystine can serve as a useful screening test, people with heterozygous defects in this gene and those who are vitamin B₉ deficient may have normal or minimally elevated levels. A much more sensitive method involves obtaining a second measurement 4 hours after the patient consumes methionine; the prevalence of hyperhomocystinemia is twice as great when this method is used. In hyperhomocystinemia, the endothelial lining of the vessel walls is denuded; this can precipitate unnecessary thrombus formation. Recent studies have determined that this disorder is much more common than previously thought. In a long-term epidemiologic study on nurses’ health (Rimm et al., 1998), women who used dietary supplements with folic acid and vitamin B₉ were found to have a lower incidence of thrombotic conditions such as DVT. Patients who are found to have hyperhomocystinemia should receive folic acid, B₉, and/or B₁₂ supplements and should be instructed in the rationale for their use to enhance compliance.

* Protein C and protein S are vitamin K–dependent proteins. Warfarin (Coumadin) interferes with the hepatic synthesis of vitamin K–dependent factors, which may decrease levels of protein C or protein S; therefore, protein C and protein S should be measured while the patient is off warfarin.

ANTITHROMBIN III DEFICIENCY

Antithrombin is a protein that inhibits thrombin and certain coagulation factors. AT III deficiency is an extremely common hereditary condition that can cause venous thrombosis, particularly when the level is less than 60% of normal. Patients with AT III deficiency can develop venous thrombosis as young adults; by 50 years of age, two thirds of patients with AT III deficiency have developed a venous thrombosis. The most common sites for thrombosis are the deep veins of the leg and the mesentery. Recurrent thrombosis often occurs. There is an increased resistance to heparin anticoagulation, so these patients may require greater amounts of heparin to achieve adequate anticoagulation. Patients with AT III deficiency should be encouraged to have their family members tested for the deficiency.

PROTEIN C DEFICIENCY

Protein C is an enzyme that, when activated, inhibits coagulation. When levels of Protein C are deficient, the risk of thrombosis increases, and thrombosis can often occur spontaneously. Protein C deficiency is at least as prevalent as AT III deficiency, and people who are Protein C–deficient can develop thrombosis early in life, as early as 15 years of age. Warfarin-induced skin necrosis is a rare but significant complication of anticoagulation management in patients with Protein C deficiency (Hoffman et al., 2000). This complication appears to result from progressive thrombosis in the capillaries within the skin; the extent of the necrosis can be extreme.

ACTIVATED PROTEIN C RESISTANCE AND FACTOR V LEIDEN MUTATION

Activated protein C (APC) resistance is a common condition that can occur with other hypercoagulable states. APC is an anticoagulant, and resistance to APC increases the risk for venous thrombosis. A molecular defect in the factor V gene has been identified in...
Along with administering anticoagulant therapy, concerns in the following section. The primary method of treating thrombotic disorders is anticoagulation. However, in thrombophilic conditions, the use of postmenopausal hormone therapy in women increases the risk for thrombosis. When the level of Protein S is deficient, this inactivation process is diminished, and the risk for thrombosis can be increased. Like patients with Protein C deficiency, those with Protein S deficiency have a greater risk for recurrent venous thrombosis at a young age, as young as 15 years.

**ACQUIRED THROMBOPHILIA**

Antibodies to phospholipids are common, acquired causes for thrombophilia (hypercoagulable states). The most common antibodies present against phospholipids are either lupus or antiphospholipid antibodies. Both of these antibodies can be transient, resulting from infection or certain medications. Most thrombotic events are venous, but arterial thrombosis can occur in up to one third of the cases. Patients who persistently test positive for either antibody and who have had a thrombotic event are at significant risk for recurrent thrombosis (greater than 50%). Recurrent thromboses tend to be of the same type—that is, venous thrombosis after an initial venous thrombosis, arterial thrombosis after an initial arterial thrombosis.

Another common acquired cause for thrombophilia is cancer. Specific types of stomach, pancreatic, lung, and ovarian cancers are most commonly associated with thrombophilia. The type of thrombosis that results is unusual. Rather than deep vein thrombosis or pulmonary embolism, the thrombosis occurs in unusual sites, such as the portal, hepatic, or renal vein or the inferior vena cava. Migratory superficial thrombophlebitis or nonbacterial thrombotic endocarditis can also occur. In these patients, anticoagulation can be difficult to manage in that the thrombosis can progress despite standard amounts of anticoagulation.

**Medical Management**

The primary method of treating thrombotic disorders is anticoagulation. However, in thrombophilic conditions, when to treat (prophylaxis or not) and how long to treat (lifelong or not) can be controversial. Anticoagulation therapy is not without risks; the most significant risk is bleeding. Risks of anticoagulation therapy are identified in Chapter 31. The most common anticoagulant medications are identified in the following section.

**PHARMACOLOGIC THERAPY**

Along with administering anticoagulant therapy, concerns include minimizing any risk factors that predispose a patient to thrombosis. When risk factors (eg, immobility after surgery, pregnancy) cannot be avoided, prophylactic anticoagulation may be necessary.

**Unfractionated Heparin Therapy.** Heparin is a naturally occurring anticoagulant that enhances AT III and inhibits platelet function. To prevent thrombosis, heparin is typically given as a subcutaneous injection, two or three times daily. To treat thrombosis, heparin is usually administered intravenously. The therapeutic effect of heparin is monitored by serial measurements of the activated partial prothrombin time; the dose is adjusted to maintain the range at 1.5 to 2.5 times the laboratory control. Oral forms are being evaluated, but their absorption remains variable (Money & York, 2001).

A significant potential complication of heparin-based therapy is heparin-induced thrombocytopenia (HIT). Antibodies are formed within the body against the heparin complex. The actual incidence of HIT is unknown, but it is thought to occur in as many as 5% patients receiving heparin (Kelton, 1999). Whereas most patients remain asymptomatic, a significant proportion of those individuals with serologic HIT develop actual thrombocytopenia. A decline in platelet count typically develops after 5 to 8 days of heparin therapy, and the platelets can drop significantly, although in most instances the level stays higher than 50,000/mm³. These patients are at increased risk for thrombosis, either venous or arterial, and the thrombosis can range from DVT to myocardial infarction, CVA (brain attack, stroke), and ischemic damage to an extremity necessitating amputation. The risk for development of HIT appears to be increased when heparin is used at higher concentrations (ie, therapeutic versus prophylactic dosage) and with preexisting comorbidity, such as underlying cardiac disease.

**Low-Molecular-Weight Heparin Therapy.** Low molecular-weight heparin (LMWH; eg, Dalteparin, Enoxaparin) is a special form of heparin that has a more selective effect on coagulation. Based on its biochemical properties, LMWH has a longer half-life and a less variable anticoagulant response than does standard heparin. These differences permit LMWH to be safely administered only once or twice daily, without the need for laboratory monitoring for dose adjustments. The incidence of HIT is much lower when LMWH is used. In certain conditions, the use of LMWH has allowed anticoagulation therapy to be moved entirely to the outpatient setting. Many cases of unexplained DVT are being managed outside the hospital setting. LMWH is also being increasingly used as “bridge therapy” when patients receiving anticoagulation therapy (warfarin) require an invasive procedure (eg, biopsy, surgery). In this situation, warfarin is stopped and LMWH is used in its place until the procedure is completed. After the procedure, warfarin therapy is resumed. LMWH is discontinued after a therapeutic level of warfarin is achieved.

**Warfarin (Coumadin) Therapy.** Coumarin anticoagulants (warfarin; eg, Coumadin) are antagonists of vitamin K and therefore interfere with the synthesis of vitamin K–dependent clotting factors. Coumarin anticoagulants bind to albumin, are metabolized in the liver, and have an extremely long half-life. Typically, a patient is initially treated with both heparin (either the unfractionated form or LMWH) and warfarin. When the international normalized ratio (INR) reaches the desired therapeutic range, the heparin is stopped. The dosage required to maintain the thera-
throughout the day, particularly during long trips by car or plane. Exercise, especially ambulation, should be performed frequently to promote circulatory stasis (e.g., immobility, crossing the legs). Patients with thrombotic disorders should avoid activities that interact with warfarin.

**Nursing Management**

Patients with thrombotic disorders should avoid activities that promote circulatory stasis (e.g., immobility, crossing the legs). Exercise, especially ambulation, should be performed frequently throughout the day, particularly during long trips by car or plane.

</table>

Medications that alter platelet aggregation, such as low-strength aspirin, may be prescribed. Some patients require life-long therapy with anticoagulants such as warfarin (e.g., Coumadin).

Patients with thrombotic disorders, particularly those with thrombophilia, should be assessed for concurrent risk factors for thrombosis and should avoid concomitant risk factors if possible. For example, use of tobacco and nicotine products exacerbates the problem and should be avoided.

Just as for other conditions, patients with thrombotic disorders, particularly thrombophilia, should know the name of their specific condition and understand its significance. In many instances, younger patients with thrombophilia may not require prophylactic anticoagulation; however, with concomitant risk factors (e.g., pregnancy), increasing age, or subsequent thrombotic events, prophylactic or lifelong anticoagulation therapy may be required. Being able to provide the health care provider with an accurate health history can be extremely useful and can help guide the selection of appropriate therapeutic interventions. Patients with hereditary disorders should be encouraged to have their siblings and children tested for the disorder.

When patients with thrombotic disorders are hospitalized, frequent assessments should be performed for signs and symptoms of beginning thrombus formation, particularly in the legs (DVT) and lungs (pulmonary embolism). Ambulation or range-of-motion exercises as well as the use of elastic compression stockings should be initiated promptly to decrease stasis. Prophylactic anticoagulants are commonly prescribed.

**Therapies for Blood Disorders**

**Splenectomy**

The surgical removal of the spleen (splenectomy) is sometimes necessary after trauma to the abdomen. Because the spleen is very vascular, severe hemorrhage can result if the spleen is ruptured. Under such circumstances, splenectomy becomes an emergency procedure.

Splenectomy is also a possible treatment for other hematologic disorders. For example, an enlarged spleen may be the site of excessive destruction of blood cells. If the destruction is life-threatening, surgery may be lifesaving. This is the case in autoimmune hemolytic anemia or ITP when these disorders do not respond to more conservative measures, such as corticosteroid therapy. Some patients with severe anemia due to inherited RBC defects (e.g., thalassemia) may also benefit from splenectomy.

In general, the mortality rate after splenectomy is low. Laparoscopic splenectomy can be used in selected patients, with a resultant decrease in the postoperative morbidity rate. Complications that may result from surgery are atelectasis, pneumonia, abdominal distention, and abscess formation. Although young children are at the highest risk after splenectomy, all age groups are vulnerable to overwhelming lethal infections and should receive pneumovax before undergoing this surgical procedure if possible.

Patients are instructed to seek prompt medical attention if even relatively minor symptoms of infection occur. Often, patients with high platelet counts have even higher counts after splenectomy—more than 1 million/mm³—which can predispose them to serious thrombotic or hemorrhagic problems. This increase is, however, transient.
THERAPEUTIC APHERESIS

Apheresis is a Greek word meaning separation. In therapeutic apheresis (or pheresis), blood is taken from the patient and passed through a centrifuge, where a specific component is separated from the blood and removed (Table 33-9). The remaining blood is then returned to the patient. The entire system is closed, so the risk of bacterial contamination is extremely low. When platelets or WBCs are removed, the decrease in these cells within the circulation is temporary. However, the temporary decrease provides a window of time until suppressive medications (eg, chemotherapy) can have therapeutic effects. Sometimes plasma is removed rather than blood cells—typically so that specific, abnormal proteins within the plasma will be transiently lowered until a long-term therapy can be initiated.

Apheresis is also used to obtain larger amounts of platelets from a donor than can be provided from a single unit of whole blood. A unit of platelets obtained in this way is equivalent to that obtained from a donor via standard blood donation methods. Platelet donors can have their platelets apheresed as often as every 14 days.

Therapeutic phlebotomy is similar to that for blood donation (see later discussion). In the past, iron absorption (eg, hemochromatosis) can usually be managed by periodically removing 1 unit (about 500 mL) of whole blood. Eventually this process can produce iron deficiency, leaving the patient unable to produce as many RBCs. The actual procedure for therapeutic phlebotomy is similar to that for blood donation (see later discussion).

BLOOD AND BLOOD COMPONENT THERAPY

A single unit of whole blood contains 450 mL of blood and 50 mL of an anticoagulant. A unit of whole blood can be processed and dispensed for administration. However, it is more appropriate, economical, and practical to separate that unit of whole blood into its primary components: RBCs, platelets, and plasma (WBCs are rarely used; see later discussion). Platelet donors can have their platelets apheresed as often as every 14 days. WBCs can be obtained similarly, typically after the donor has received growth factors (G-CSF, GM-CSF) to stimulate the formation of additional WBCs and thereby increase the WBC count. The use of these growth factors also stimulates the release of stem cells within the circulation. Apheresis is used to harvest these stem cells (typically over a period of several days) for use in PBSCT (peripheral blood stem cell transplant; see Chap. 16).

THERAPEUTIC PHLEBOTOMY

Therapeutic phlebotomy is the removal of a certain amount of blood under controlled conditions. Patients with elevated hematocrits (eg, those with polycythemia vera) or excessive iron absorption (eg, hemochromatosis) can usually be managed by periodically removing 1 unit (about 500 mL) of whole blood. Eventually this process can produce iron deficiency, leaving the patient unable to produce as many RBCs. The actual procedure for therapeutic phlebotomy is similar to that for blood donation (see later discussion).

BLOOD AND BLOOD COMPONENT THERAPY

A single unit of whole blood contains 450 mL of blood and 50 mL of an anticoagulant. A unit of whole blood can be processed and dispensed for administration. However, it is more appropriate, economical, and practical to separate that unit of whole blood into its primary components: RBCs, platelets, and plasma (WBCs are rarely used; see later discussion). Platelet donors can have their platelets apheresed as often as every 14 days. WBCs can be obtained similarly, typically after the donor has received growth factors (G-CSF, GM-CSF) to stimulate the formation of additional WBCs and thereby increase the WBC count. The use of these growth factors also stimulates the release of stem cells within the circulation. Apheresis is used to harvest these stem cells (typically over a period of several days) for use in PBSCT (peripheral blood stem cell transplant; see Chap. 16).

SPECIAL PREPARATIONS

Factor VIII concentrate (antihemophilic factor) is a lyophilized, freeze-dried concentrate of pooled fractionated human plasma. It is used in treating hemophilia A. Factor IX concentrate (prothrombin complex) is similarly prepared and contains factors II, III, VII, IX, and X, plus fibrinogen.

| Table 33-9 • Types of Apheresis* |
|-------------------------------|----------------|---------------------------------|
| PROCEDURE                     | PURPOSE         | EXAMPLES OF CLINICAL USE         |
| Platelet pheresis             | Remove platelets| Extreme thrombocytosis, essential thrombocytopenia (temporary measure); single-donor platelets transfusion |
| Leukapheresis                 | Remove WBCs (can be specific to neutrophils or lymphocytes) | Extreme leukocytosis (eg, AML, CML) (very temporary measure); harvest WBCs for transfusion |
| Erythrocytapheresis (RBC exchange) | Remove RBCs | RBC dyscrasias (eg, sickle cell disease); RBCs replaced via transfusion |
| Plasmapheresis (plasma exchange) | Remove plasma proteins | Hyperviscosity syndromes; treatment for some renal and neurologic diseases (eg, Goodpasture’s syndrome, Guillain-Barré) |
| Stem cell harvest             | Remove circulating stem cells | Transplantation (donor harvest or autologous) |

*Therapeutic apheresis can be used to treat a wide variety of conditions. When it is used to treat a disease that causes an increase in a specific cell type with a short life in circulation (ie, WBCs, platelets), the reduction in those cells is temporary. However, this temporary reduction permits a margin of safety while waiting for a longer-lasting treatment modality (eg, chemotherapy) to take effect. Apheresis can also be used to obtain stem cells for transplantation, either from a matched donor (allogeneic) or from the patient (autologous). AML, acute myeloid leukemia; CML, chronic myeloid leukemia; RBC, red blood cell; WBC, white blood cell.
VII, IX, and X. It is used primarily for treatment of factor IX deficiency (hemophilia B). Factor IX concentrate is also useful in treating congenital factor VII and factor X deficiencies.

Plasma albumin is a large protein molecule that usually stays within vessels and is a major contributor to plasma oncotic pressure. This protein is used to expand the blood volume of patients in hypovolemic shock and, rarely, to increase the concentration of circulating albumin in patients with hypoalbuminemia.

Immune globulin is a concentrated solution of the antibody IgG; it contains very little IgA or IgM. It is prepared from large pools of plasma. The intravenous form (IVIG) is used in various clinical situations to replace inadequate amounts of IgG in patients who are at risk for recurrent bacterial infection (eg, those with CLL, those receiving BMT or PBSCT). IVIG, in contrast to all other fractions of human blood, cells, or plasma, are able to survive being subjected to heating at 60°C (140°F) for 10 hours to free them of viral contaminants.

* The composition of each type of blood component is described as well as the most common indications for using a given blood component. RBCs, platelets, and fresh frozen plasma are the blood products most commonly used. When transfusing these blood products, it is important to realize that the individual product is always “contaminated” with very small amounts of other blood products (eg, WBCs mixed in a unit of platelets). This contamination can cause some difficulties, particularly isoimmunization, in certain patients. AHF, antihemophilic factor; CLL, chronic lymphocytic leukemia; ITP, idiopathic thrombocytopenic purpura.

**BLOOD DONATION**

To protect both the donor and the recipients, all prospective donors are examined and interviewed before they are allowed to donate their blood. The intent of the interview is to assess the general health status of the donor and to identify risk factors that might harm a recipient of the donor’s blood. Donors should be in good health and without any of the following:

- A history of viral hepatitis at any time in the past, or a history of close contact with a hepatitis or dialysis patient within 6 months
- A history of receiving a blood transfusion or an infusion of any blood derivative (other than serum albumin) within 6 months
- A history of untreated syphilis or malaria, because these diseases can be transmitted by transfusion even years later. A
person who has been free of symptoms and off therapy for 3 years after malaria may be a donor.

- A history or evidence of drug abuse in which substances were self-injected, because many intravenous/injection drug users are hepatitis carriers and because the risk for human immunodeficiency virus (HIV) is high in this group
- A history of possible exposure to HIV; the population at risk includes people who engage in anal sex, people with multiple sexual partners, intravenous/injection drug users, sexual partners of people at risk for HIV, and people with hemophilia
- A skin infection, because of the possibility of contaminating the phlebotomy needle, and subsequently the blood itself
- A history of recent asthma, urticaria, or allergy to medications, because hypersensitivity can be transferred passively to the recipient
- Pregnancy within 6 months, because of the nutritional demands of pregnancy on the mother
- A history of tooth extraction or oral surgery within 72 hours, because such procedures are frequently associated with transient bacteremia
- A history of exposure to infectious disease within the past 3 weeks, because of the risk of transmission to the recipient
- Recent immunizations, because of the risk of transmitting live organisms (2-week waiting period for live, attenuated organisms; 1 month for rubella; 1 year for rabies)
- A history of recent tattoo, because of the risk of blood-borne infections (e.g., hepatitis, HIV)
- Cancer, because of the uncertainty about transmission of the disease
- A history of whole blood donation within the past 56 days

Potential donors should be asked whether they have consumed any aspirin or aspirin-containing medications within the past 3 days. Although aspirin use does not render the donor ineligible, the platelets obtained would be dysfunctional and therefore not useful. Aspirin does not affect the RBCs or plasma obtained from the donor.

All donors are expected to meet the following minimal requirements:

- Body weight should exceed 50 kg (110 pounds) for a standard 450-mL donation. Donors weighing less than 50 kg donate proportionately less blood. People younger than 17 years of age are disqualified from donation.
- The oral temperature should not exceed 37.5°C (99.6°F).
- The pulse rate should be regular and between 50 and 100 beats per minute.
- The systolic arterial pressure should be 90 to 180 mm Hg, and the diastolic pressure should be 50 to 100 mm Hg.
- The hemoglobin level should be at least 12.5 g/dL for women and 13.5 g/dL for men.

**Directed Donation**

At times, friends and family of a patient wish to donate blood for that person. These blood donations are termed directed donations. These donations are not any safer than those provided by random donors, because directed donors may not be as willing to identify themselves as having a history of any of the risk factors that disqualify a person from donating blood.

**Standard Donation**

Phlebotomy consists of venipuncture and blood withdrawal. Standard precautions are used. Donors are placed in a semirecumbent position. The skin over the antecubital fossa is carefully cleansed with an antiseptic preparation, a tourniquet is applied, and venipuncture is performed. Withdrawal of 450 mL of blood usually takes less than 15 minutes. After the needle is removed, donors are asked to hold the involved arm straight up, and firm pressure is applied with sterile gauze for 2 or 3 minutes or until bleeding stops. A firm bandage is then applied. Donors remain recumbent until they feel able to sit up, usually within a few minutes. Donors who experience weakness or faintness should rest for a longer period. Donors then receive food and fluids and are asked to remain another 15 minutes.

Donors are instructed to leave the dressing on and to avoid heavy lifting for several hours, to avoid smoking for 1 hour, to avoid drinking alcoholic beverages for 3 hours, to increase fluid intake for 2 days, and to eat a healthy meal for 2 weeks. Specimens from this donated blood are tested to detect infections and to identify the specific blood type (see later discussion).

**Autologous Donation**

A patient’s own blood may be collected for future transfusion; this method is useful for many elective surgeries where the potential need for transfusion is high (e.g., orthopedic surgery). Preoperative donations are ideally collected 4 to 6 weeks before surgery. Iron supplements are prescribed during this period to prevent depletion of iron stores. Occasionally, erythropoietin (epoetin-alfa [Epogen, Procrit]) is given to stimulate erythropoiesis to ensure that the donor’s hematocrit remains high enough to be eligible for donation. Typically, 1 unit of blood is drawn each week; the number of units obtained varies with the type of surgical procedure to be performed (i.e., the amount of blood anticipated to be transfused). Phlebotomies are not performed within 72 hours of surgery. Individual blood components can also be collected.

The primary advantage of autologous transfusions is the prevention of viral infections from another person’s blood. Other advantages include a safer transfusion for patients with a history of transfusion reactions, prevention of alloimmunization, and avoidance of complications in patients with alloantibodies. The policy of the American Red Cross requires autologous blood to be transfused only to the donor. If the blood is not required, it can be frozen until the donor needs it in the future (for up to 10 years). The blood is never returned to the general donor supply of blood products to be used by someone else.

The disadvantage of autologous donation is that it may be performed even when the likelihood that the anticipated procedure will necessitate a transfusion is small. Needless autologous donation is expensive, takes time, and uses resources inappropriately. Moreover, in an emergency situation, the autologous units available may be inadequate, and the patient may still require additional units from the general donor supply.

Contraindications to donation of blood for autologous transfusion are acute infection, severely debilitating chronic disease, hemoglobin level less than 11 g/dL, hematocrit less than 33%, unstable angina, and acute cardiovascular or cerebrovascular disease. A history of poorly controlled epilepsy may be considered a contraindication in some centers. Patients with cancer may donate for themselves.
Intraoperative Blood Salvage

This transfusion method provides replacement for patients who are unable to donate before surgery and for those undergoing vascular, orthopedic, or thoracic surgery. During a surgical procedure, blood lost into a sterile cavity (eg, hip joint) is suctioned into a cell-saver machine. The RBCs are washed, often with saline solution, and then returned to the patient as an intravenous infusion. Salvaged blood cannot be stored, because bacteria cannot be completely removed from the blood.

Hemodilution

This transfusion method is initiated before or after induction of anesthesia. About 1 or 2 units of blood are removed from the patient through a venous or arterial line and simultaneously replaced with a colloid or crystalloid solution. The blood obtained is then reinfused after surgery (Kreimeier & Messmer, 2002). The advantage of this method is that the patient loses fewer RBCs during surgery, because the added intravenous solutions dilute the concentration of RBCs and lower the hematocrit. Patients who are at risk for myocardial injury, however, should not be further stressed by hemodilution.

COMPLICATIONS OF BLOOD DONATION

Excessive bleeding at the donor’s venipuncture site is sometimes caused by a bleeding disorder in the donor but more often results from a technique error: laceration of the vein, excessive tourniquet pressure, or failure to apply enough pressure after the needle is withdrawn.

Fainting is common after blood donation and may be related to emotional factors, a vasovagal reaction, or prolonged fasting before donation. Because of the loss of blood volume, hypotension and syncope may occur when the donor assumes an erect position. A donor who appears pale or complains of faintness should immediately lie down or sit with head lowered below the knees; he or she should be observed for another 30 minutes.

Anginal chest pain may be precipitated in patients with unsuspected coronary artery disease. Seizures can occur in donors with epilepsy, although the incidence is very low. Both angina and seizures require further medical evaluation.

Many people have the misconception that donating blood can cause AIDS and other infections. Potential donors need to be educated that the equipment used in donation is sterile, a closed system, and not reusable; they are at no risk for acquiring such infections from donating blood.

BLOOD PROCESSING

Samples of the unit of blood are always taken immediately after donation so that the blood can be typed and tested. Each donation is tested for antibodies to HIV 1 and 2, hepatitis B core antibody (anti-HBc), hepatitis C virus (HCV), and human T-cell lymphotropic virus, type I (anti-HTLV-I/II). The blood is also tested for hepatitis B surface antigen (HbsAg) and for syphilis. Negative reactions are required for the blood to be used, and each unit of blood is labeled to certify the results. A new testing method, using nucleic acid amplification testing (NAT), has increased the ability to detect the presence of HCV and HIV infection, because it directly tests for genomic nucleic acids of the virus itself, rather than for the presence of antibodies to the virus (Korman, Leparc & Benson, 2001). This testing significantly shortens the “window” of inability to detect HIV and HCV from a donated unit, further ensuring the safety of the blood. Blood is also screened for CMV; if it tests positive for CMV, it can still be used, except in recipients who are negative for CMV and who are immunocompromised (eg, BMT or PBSC/T recipients).

Equally important to viral testing is accurate determination of the blood type. More than 200 antigens have been identified on the surface of RBC membranes. Of these, the most important for safe transfusion are the ABO and Rh systems. The ABO system identifies which sugars are present on the membrane of an individual’s RBCs: A, B, both A and B, or neither A nor B (type O). To prevent a significant reaction, the same type of RBCs should be transfused. Previously, it was thought that in an emergency situation in which the patient’s blood type was not known, type O blood could be safely transfused. This practice is no longer advised by the American Red Cross.

The Rh antigen (also called D) is present on the surface of RBCs in 85% of the population (Rh-positive). Those who lack the D antigen are called Rh-negative. RBCs are routinely tested for the D antigen as well as ABO. Patients should receive PRBCs with a compatible Rh type.

TRANSFUSION

Administration of blood and blood components requires knowledge of correct administration techniques and possible complications. It is very important to be familiar with the agency’s policies and procedures for transfusion therapy. Methods for transfusing blood components are presented in Charts 33-16 and 33-17. Potential complications of transfusion follow.

Setting

Although most blood transfusions are performed in the acute care setting, patients with chronic transfusion requirements often can receive transfusions in other settings. Free-standing infusion centers, ambulatory care clinics, a physician’s office, and even the home may be appropriate settings for transfusion. Typically, patients who need chronic transfusions but are otherwise stable physically are appropriate candidates for outpatient therapy. Verification and administration of the blood product are performed much as in a hospital setting. Although most blood products can be transfused in the outpatient setting, the home is typically limited to transfusions of PRBCs and factor components (eg, factor VIII for patients with hemophilia).

Pretransfusion Assessment

PATIENT HISTORY

Patient history is an important component of the pretransfusion assessment to determine the history of previous transfusions as well as previous reactions to transfusion. The history should include the type of reaction, its manifestations, the interventions required, and whether any preventive interventions were used in subsequent transfusions. It is important to assess the number of pregnancies a woman has had, because an increased number can increase her risk for reaction due to antibodies developed from exposure to fetal circulation. Other concurrent health problems should also be noted, with careful attention to cardiac, pulmonary, and vascular disease.
Transfusion of Packed Red Blood Cells (PRBCs)

**Preprocedure**
1. Confirm that the transfusion has been prescribed.
2. Check that patient’s blood has been typed and cross-matched.
3. Verify that patient has signed a written consent form per institution policy.
4. Explain the procedure to the patient. Instruct patient in signs and symptoms of transfusion reaction (itching, hives, swelling, shortness of breath, fever, chills).
5. Take patient’s temperature, pulse, respiration, and blood pressure to establish a baseline for comparing vital signs during transfusion.
6. Use hand hygiene and wear gloves in accordance with Standard Precautions.
7. Use a 20-gauge or larger needle for placement in a large vein. Use special tubing that contains a blood filter to screen out fibrin clots and other particulate matter. Do not vent the blood container.

**Procedure**
1. Obtain the PRBCs from the blood bank after the intravenous line is started. (Institution policy may limit release to only 1 unit at a time.)
2. Double-check the labels with another nurse or physician to make sure that the ABO group and Rh type agree with the compatibility record. Check to see that the number and type on the donor blood label and on the patient’s chart are correct. Check the patient’s identification by asking the patient’s name and checking the identification wristband.
3. Check the blood for gas bubbles and any unusual color or cloudiness. (Gas bubbles may indicate bacterial growth. Abnormal color or cloudiness may be a sign of hemolysis.)

**Note:** Never add medications to blood or blood products; if blood is too thick to run freely, normal saline may be added to the unit. If blood must be warmed, use an in-line blood warmer with a monitoring system.

**Postprocedure**
1. Obtain vital signs and compare with baseline measurements.
2. Dispose of used materials properly.
3. Document procedure in patient’s medical record, including patient assessment findings and tolerance to procedure.
5. For first 15 minutes, run the transfusion slowly—no faster than 5 mL/min. Observe the patient carefully for adverse effects. If no adverse effects occur during the first 15 min, increase the flow rate unless the patient is at high risk for circulatory overload.
6. Monitor closely for 15–30 min to detect signs of reaction. Monitor vital signs at regular intervals per institution policy; compare results with baseline measurements. Increase frequency of measurements based on patient’s condition. Observe the patient frequently throughout the transfusion for any signs of adverse reaction, including restlessness, hives, nausea, vomiting, torso or back pain, shortness of breath, flushing, hematuria, fever, or chills. Should any adverse reaction occur, stop infusion immediately, notify physician, and follow the agency’s transfusion reaction standard.
7. Note that administration time does not exceed 4 hr because of the increased risk for bacterial proliferation.
8. Be alert for signs of adverse reactions: circulatory overload, sepsis, febrile reaction, allergic reaction, and acute hemolytic reaction.
9. Change blood tubing after every 2 units transfused, to decrease chance of bacterial contamination.

Transfusion of Platelets or Fresh Frozen Plasma (FFP)

**Preprocedure**
1. Confirm that the transfusion has been prescribed.
2. Verify that patient has signed a written consent form per institution policy.
3. Explain the procedure to the patient. Instruct patient in signs and symptoms of transfusion reaction (itching, hives, swelling, shortness of breath, fever, chills).
4. Take patient’s temperature, pulse, respiration, and blood pressure to establish a baseline for comparing vital signs during transfusion.
5. Wash hands and wear gloves in accordance with Standard Precautions.
6. Use a 22-gauge or larger needle for placement in a large vein, if possible. Use appropriate tubing per institution policy (platelets often require different tubing from that used for other blood products).

**Procedure**
1. Obtain the platelets or FFP from the blood bank (only after the intravenous line is started.)
2. Double-check the labels with another nurse or physician to make sure that the ABO group matches the compatibility record (not usually necessary for platelets; here only if compatible platelets are ordered). Check to see that the number and type on the donor blood label and on the patient’s chart are correct. Check the patient’s identification by asking the patient’s name and checking the identification wristband.
3. Check the blood product for any unusual color or clumps (excessive redness indicates contamination with larger amounts of red blood cells).

**Note:** FFP requires ABO but not Rh compatibility. Platelets are not typically cross-matched for ABO compatibility. Never add medications to blood or blood products.

**Postprocedure**
1. Obtain vital signs and compare with baseline measurements.
2. Dispose of used materials properly.
3. Document procedure in patient’s medical record, including patient assessment findings and tolerance to procedure.
5. Make sure platelets or FFP units are administered immediately after they are obtained.
6. Infuse each unit as fast as patient can tolerate to diminish platelet clumping during administration. Observe the patient carefully for adverse effects, including circulatory overload. Decrease rate of infusion if necessary.
7. Observe the patient closely throughout the transfusion for any signs of adverse reaction, including restlessness, hives, nausea, vomiting, torso or back pain, shortness of breath, flushing, hematuria, fever, or chills. Should any adverse reaction occur, stop infusion immediately, notify physician, and follow the agency’s transfusion reaction standard.
8. Monitor vital signs at end of transfusion per institution policy; compare results with baseline measurements.
9. Flush line with saline after transfusion to remove blood component from tubing.
PHYSICAL ASSESSMENT
A systematic physical assessment and measurement of baseline vital signs are important before transfusing any blood product. The respiratory system should be assessed, including careful auscultation of the lungs and for use of accessory muscles. Cardiac system assessment should include careful inspection for any edema as well as other signs of cardiac failure (eg, jugular venous distention). The skin should be observed for rashes, petechiae, and ecchymoses. The sclera should be examined for icterus. In the event of a possible transfusion reaction, a comparison of findings can help differentiate between types of reactions.

Patient Teaching
Reviewing the signs and symptoms of a potential transfusion reaction is crucial for patients who have not received a transfusion before. Even for those patients who have received prior transfusions, a brief review of signs and symptoms of potential transfusion reactions is advised. Signs and symptoms of a possible reaction include fever, chills, respiratory distress, low back pain, nausea, pain at the intravenous site, or anything “unusual.” Although a thorough review is very important, it is also important to reassure the patient that the blood is carefully tested against the patient’s own blood (cross-matched) to diminish the likelihood of any untoward reaction. Such assurance can be extremely beneficial in allaying anxiety. Similarly, it can be useful to mention again the very low possibility of contracting HIV from the transfusion; this fear persists among many people.

Transfusion Complications
Any patient who receives a blood transfusion may develop complications from that transfusion. When explaining the reasons for the transfusion, it is important to include the risks and benefits and what to expect during and after the transfusion. Patients must be informed that the supply of blood is not completely risk-free although it has been tested carefully. Nursing management is directed toward preventing complications, promptly recognizing complications if they develop, and promptly initiating measures to control any complications that occur. The following sections describe the most common or potentially severe transfusion-related complications.

FEBRILE, NONHEMOLYTIC REACTION
The nonhemolytic reaction, caused by antibodies to donor WBCs that are still present in the unit of blood or blood component, is the most common type of transfusion reaction, accounting for more than 90% of reactions. It occurs more frequently in patients who have had previous transfusions (exposure to multiple antigens from previous blood products) and in Rh-negative women who have borne Rh-positive children (exposure to an Rh-positive fetus raises antibody levels in the mother). These reactions occur in 1% of PRBC transfusions and 20% of platelet transfusions. More than 10% of patients with a chronic transfusion requirement develop this type of reaction.
The diagnosis of a febrile, nonhemolytic reaction is made by excluding other potential causes, such as a hemolytic reaction or bacterial contamination of the blood product. The signs and symptoms of a febrile, nonhemolytic transfusion reaction are chills (absent to severe) followed by fever (more than 1°C elevation). The fever typically begins within 2 hours after the transfusion is begun. Although not life-threatening, the fever and particularly the chills and muscle stiffness can be frightening to the patient.

These reactions can be diminished, even prevented, by further depleting the blood component of donor WBCs; this is accomplished by a leukocyte reduction filter. The blood product may be filtered during processing, which achieves better results but is more expensive, or during the actual transfusion by adding the filter to the blood administration tubing. Antipyretics can be given to prevent fever, but routine premedication is not advised because it can mask the beginning of a more serious transfusion reaction.

ACUTE HEMOLYTIC REACTION

The most dangerous, and potentially life-threatening, type of transfusion reaction occurs when the donor blood is incompatible with that of the recipient. Antibodies already present in the recipient’s plasma rapidly combine with antigens on donor RBCs, and the RBCs are hemolyzed (destroyed) in the circulation (intravascular hemolysis). The most rapid hemolysis occurs in ABO incompatibility. This reaction can occur after transfusion of as little as 10 mL of RBCs. Rh incompatibility often causes a less severe reaction. The most common causes of acute hemolytic reaction are errors in blood component labeling and patient identification that result in the administration of an ABO-incompatible transfusion.

Symptoms consist of fever, chills, low back pain, nausea, chest tightness, dyspnea, and anxiety. As the RBCs are destroyed, the hemoglobin is released from the cells and excreted by the kidneys; therefore, hemoglobin is present in the urine (hemoglobinuria). Hypotension, bronchospasm, and vascular collapse may result. Diminished renal perfusion results in acute renal failure, and DIC may also occur.

The reaction must be recognized promptly and the transfusion discontinued immediately. Blood and urine specimens must be obtained and analyzed for evidence of hemolysis. Treatment goals include maintaining blood volume and renal perfusion and preventing and managing DIC.

Acute hemolytic transfusion reactions are preventable. Meticulous attention to detail in labeling blood samples and blood components and identifying the recipient cannot be overemphasized.

ALLERGIC REACTION

Some patients may develop urticaria (hives) or generalized itching during a transfusion. The cause of these reactions is thought to be a sensitivity reaction to a plasma protein within the blood component being transfused. Symptoms of an allergic reaction are urticaria, itching, and flushing. The reactions are usually mild and respond to antihistamines. If the symptoms resolve after administration of an antihistamine (eg, diphenhydramine [eg, Benadryl]), the transfusion may be resumed. Rarely, the allergic reaction is severe, with bronchospasm, laryngeal edema, and shock. These reactions are managed with epinephrine, corticosteroids, and pressor support, if necessary.

Giving the patient antihistamines before the transfusion may prevent future reactions. For severe reactions, future blood components are washed to remove any remaining plasma proteins. Leukocyte filters are not useful, because the offending plasma proteins can pass through the filter.

CIRCULATORY OVERLOAD

If too much blood infuses too quickly, hypervolemia can occur. This condition can be aggravated in patients who already have increased circulatory volume (eg, those with heart failure). PRBCs are safer to use than whole blood. If the administration rate is insufficiently slow, circulatory overload may be prevented. For patients who are at risk for, or already in, circulatory overload, diuretics are administered after the transfusion or between units of PRBCs. Patients receiving fresh frozen plasma or even platelets may also develop circulatory overload. The infusion rate of these blood components must also be titrated to the patient’s tolerance.

Signs of circulatory overload include dyspnea, orthopnea, tachycardia, and sudden anxiety. Neck vein distention, crackles at the base of the lungs, and a rise in blood pressure can also occur. If the transfusion is continued, pulmonary edema can develop, as manifested by severe dyspnea and coughing of pink, frothy sputum.

If fluid overload is mild, the transfusion can often be continued after slowing the rate of infusion and administering diuretics. However, if the overload is severe, the patient is placed in an upright position with the feet in a dependent position, the transfusion is discontinued, and the physician is notified. The intravenous line is kept patent with a very slow infusion of normal saline solution or a saline or heparin lock device to maintain access to the vein in case intravenous medications are necessary. Oxygen and morphine may be needed for severe dyspnea.

BACTERIAL CONTAMINATION

The incidence of bacterial contamination of blood components is very low; however, administration of contaminated products puts the patient at great risk. Contamination can occur at any point during procurement or processing. Many bacteria cannot survive in the cold temperatures used to store PRBCs (platelets are at greater risk for contamination because they are stored at room temperature), but some organisms can survive cold temperatures.

Preventive measures include meticulous care in the procurement and processing of blood components. When PRBCs or whole blood is transfused, it should be administered within a 4-hour period, because warm room temperatures promote bacterial growth. A contaminated unit of blood product may appear normal, or it may have an abnormal color.

The signs of bacterial contamination are fever, chills, and hypotension. These signs may not occur until the transfusion is complete, occasionally not until several hours after the transfusion. If the condition is not treated immediately with fluids and broad-spectrum antibiotics, shock can occur. Even with aggressive management, including vasopressor support, the mortality rate is high.

As soon as the reaction is recognized, any remaining transfusion is discontinued and the intravenous line is kept open with normal saline solution. The physician and the blood bank are notified, and the blood container is returned to the blood bank for testing and culture. Septicemia is treated with intravenous fluids and antibiotics; corticosteroids and vasopressors also may be necessary.
Over time, the excess iron deposits in the tissues and can cause iron overload. Patients with chronic transfusion requirements can quickly acquire more iron than they can use, leading to iron overload. One unit of PRBCs contains 250 mg of iron.

Iron Overload. One unit of PRBCs contains 250 mg of iron. Patients with chronic transfusion requirements can quickly acquire more iron than they can use, leading to iron overload. Over time, the excess iron deposits in the tissues and can cause iron toxicity (Giardina & Grady, 1995).

DELAYED HEMOLYTIC REACTION

Delayed hemolytic reactions usually occur within 14 days after transfusion, when the level of antibody has been increased to the extent that a reaction can occur. The hemolysis of the RBCs is extravascular, via the RES, and occurs gradually.

Signs and symptoms of a delayed hemolytic reaction are fever, anemia, increased bilirubin level, decreased or absent haptoglobin, and possibly jaundice. Rarely is there hemoglobinuria. Generally, these reactions are not dangerous, but it is useful to recognize them, because subsequent transfusions with blood products containing these antibodies may cause a more severe hemolytic reaction. However, recognition is also difficult, because the patient may not be in a health care setting to be tested for this reaction, and even if the patient is hospitalized, the reaction may be too mild to be recognized clinically. Because the amount of antibody present can be too low to detect, it is difficult to prevent delayed hemolytic reactions. The reaction is usually mild and requires no intervention.

DISEASES TRANSMITTED BY BLOOD TRANSFUSION

Despite the advances in donor screening and blood testing, certain diseases can still be transmitted by transfusion of blood components. The diseases in Chart 33-18 are examples of this phenomenon.

COMPLICATIONS OF LONG-TERM TRANSFUSION THERAPY

The complications that have been described represent a real risk for any patient any time a unit of blood is administered. However, patients with long-term transfusion therapy (eg, those with MDS, thalassemia, sickle cell anemia) are at greater risk for infection transmission and for becoming more sensitized to donor antigens, simply because they are exposed to more units of blood and, consequently, more donors. Iron overload is a complication unique to those individuals with long-term PRBC transfusions. A summary of complications associated with long-term transfusion therapy is depicted in Table 33-11.

NURSING MANAGEMENT FOR TRANSFUSION REACTIONS

If a transfusion reaction is suspected, the transfusion must be immediately stopped and the physician notified. A thorough patient assessment is crucial, because many complications have similar signs and symptoms. The following steps are taken to determine the type and severity of the reaction:

- Stop the transfusion. Maintain the intravenous line with normal saline solution through new intravenous tubing, administered at a slow rate.
- Assess the patient carefully. Compare the vital signs with those from the baseline assessment. Assess the patient’s respiratory status carefully. Note the presence of adventitious breath sounds, use of accessory muscles, extent of dyspnea
(if any), and changes in mental status, including anxiety and confusion. Note any chills, diaphoresis, complaints of back pain, urticaria, and jugular vein distention.

- Notify the physician of the assessment findings, and implement any orders obtained. Continue to monitor the patient’s vital signs and respiratory, cardiovascular, and renal status.
- Notify the blood bank that a suspected transfusion reaction has occurred.
- Send the blood container and tubing to the blood bank for repeat typing and culture. The identifying tags and numbers are verified.

If a hemolytic transfusion reaction or bacterial infection is suspected, the nurse should do the following:

- Obtain appropriate blood specimens from the patient.
- Collect a urine sample as soon as possible for a hemoglobin determination.
- Document the reaction, according to the institution’s policy.

### PHARMACOLOGIC ALTERNATIVES TO BLOOD TRANSFUSIONS

Pharmacologic agents to stimulate production of one or more types of blood cells by the marrow are commonly used. Chart 33-19 presents examples of such pharmacologic agents.

Researchers continue to seek a blood substitute that is practical and safe. Blood substitutes previously tried have not been successful. However, newer blood substitutes focus solely on oxygen delivery, as an RBC substitute (Rabinovici, 2001). Current blood substitutes in clinical trials have distinct advantages and disadvantages compared with human RBCs. They are manufactured hemoglobin solutions that can be sterilized without destroying the blood substitute. They require no refrigeration and appear to have a long shelf-life (possibly 1 year, versus little more than 1 month for PRBCs). Perhaps more importantly, they require no cross-matching, because there is no RBC membrane to interact with antibodies in the recipient’s serum. The most significant disadvantage stems from the blood substitutes extremely short life within human circulation—approximately 1 day, instead of the 30-day life span of a conventionally transfused RBC. Therefore, the use of these products would likely be limited to situations in which the need is short-term (eg, surgery, trauma). Finally, the blood substitutes are likely to be extremely expensive.

### PERIPHERAL BLOOD STEM CELL TRANSPLANTATION (PBSCT) AND BONE MARROW TRANSPLANTATION (BMT)

PBSCT and BMT are therapeutic modalities that offer the possibility of cure for some patients with hematologic disorders such as severe aplastic anemia, some forms of leukemia, and thalassemia. Because most hematologic disease states arise from some form of bone marrow dysfunction, an autologous transplantation (receiving one’s own stem cells) is not as common an option as is allogeneic transplantation. A patient receives intensive chemotherapy (sometimes with radiation therapy as well), with the goal being complete ablation of the patient’s bone marrow. Stem cells from the donor (ideally, from a matched sibling), or actual marrow from the donor, is then infused into the patient using a process similar to an RBC transfusion. The stem cells travel to the marrow and slowly begin the process of resuming hematopoiesis. The advantage of autotransplantation is the reduced likelihood of complications and mortality; however, the risk of relapse is also higher.

A relatively new strategy is based on transplantation for adoptive cell therapy using certain immune mechanisms derived from the donor’s lymphocytes (Slavin et al., 2001; Margolis, Borrello, & Flinn, 2000). In nonmyeloablative stem cell or marrow transplantation, also referred to as a “minitransplant,” the conditioning regimen involves much less myelosuppression than in conventional regimens, rendering the patient immunosuppressed but for a shorter period of time. Consequently, the procedure is less toxic to the patient, and there is a significant decrease in morbidity.

After the deconditioning regimen (ie, during the time the patient is immunosuppressed), the allotransplantation is performed, using either marrow or stem cells. The goal is for the donor’s lymphocytes to react against any residual malignant cells within the patient and destroy them. This process is typically augmented by...
Growth Factors
Recombinant technology has provided a means to produce hematopoietic growth factors necessary for the production of blood cells within the bone marrow. By increasing the body’s production of blood cells, transfusions and complications resulting from diminished blood cells (eg, infection from neutropenia or transfusions) may be avoided. However, the successful use of growth factors requires functional bone marrow.

Erythropoietin
Erythropoietin (epoietin alpha [eg, Epogen, Procrit]) is an effective alternative treatment for patients with chronic anemia secondary to diminished levels of erythropoietin, as in chronic renal disease. This medication stimulates erythropoiesis. It also has been used for patients who are anemic from chemotherapy or zidovudine (AZT) therapy and for those who have diseases involving bone marrow suppression, such as myelodysplastic syndrome (MDS). The use of erythropoietin can also enable a patient to donate several units of blood for future use (eg, preoperative autologous donation). The medication can be administered intravenously or subcutaneously, although plasma levels are better sustained with the subcutaneous route. Side effects are rare, but erythropoietin can cause or exacerbate hypertension. If the anemia is corrected too quickly or is overcorrected, the elevated hematocrit can cause headache and, potentially, seizures. These adverse effects are rare except for patients with renal failure. Serial complete blood counts (CBCs) should be performed to evaluate the response to the medication. The dose and frequency of administration are titrated to the hematocrit.

Granulocyte-Colony Stimulating Factor (G-CSF)
G-CSF (filgrastim [Neupogen]) is a cytokine that stimulates the proliferation and differentiation of myeloid stem cells; a rapid increase in neutrophils is seen within the circulation. G-CSF is effective in improving transient but severe neutropenia after chemotherapy or in some forms of MDS. It is particularly useful in preventing bacterial infections that would be likely to occur with neutropenia. G-CSF is administered subcutaneously on a daily basis. The primary side effect is bone pain; this probably reflects the increase in hematopoiesis within the marrow. Serial CBCs should be performed to evaluate the response to the medication and to ensure that the rise in white blood cells is not excessive. The effect of G-CSF on myelopoiesis is short; the neutrophil count drops once the medication is stopped.

Granulocyte-Macrophage Colony Stimulating Factor (GM-CSF)
GM-CSF (sargramostim [Leukine]) is a cytokine that is naturally produced by a variety of cells, including monocytes and endothelial cells. It works either directly or synergistically with other growth factors to stimulate myelopoiesis. GM-CSF is not as specific to neutrophils as is G-CSF; thus, an increase in erythroid (RBC) and megakaryocytic (platelet) production may also be seen. GM-CSF serves the same purpose as G-CSF. However, it may have a greater effect on macrophage function and therefore may be more useful against fungal infections, whereas G-CSF may be better used to fight bacterial infections. GM-CSF is also administered subcutaneously. Side effects include bone pain, fevers, and myalgias.

Thrombopoietin
Thrombopoietin (TPO) is a cytokine that is necessary for the proliferation of megakaryocytes and subsequent platelet formation. Clinical studies have demonstrated efficacy of TPO in the setting of chemotherapy-induced thrombocytopenia with few side effects (Vadhan-Raj, 2000). Further studies are ongoing to assess the efficacy of TPO in other, more chronic conditions associated with thrombocytopenia (Kuter, 2000).

Critical Thinking Exercises
1. You are working in a hematology-oncology clinic. The laboratory reports a critical study result for one of your patients with CLL: the reticulocyte count is 25%. What other laboratory results would be important to review or consider? The patient is profoundly anemic; does this support your original thinking and problem solving? What medical treatment orders would you anticipate? What nursing interventions would be appropriate?

2. You are caring for a young adult patient who has had repeated hospitalizations for sickle cell crisis. What factors should be assessed to determine the patient’s education, coping, and pain management needs? What is important for the patient’s discharge plan?

3. You are caring for a patient diagnosed with leukemia. The family members are very concerned about the patient’s risk for infection at home. What assessments will assist you to determine the patient’s risk of developing an infection at home? What instructions should you give about decreasing the risks for infection? How would you alter your interventions if the family members are not fluent in English?

4. You are caring for a patient who is septic and is now receiving a transfusion of 2 units of PRBCs. The patient’s temperature spikes to 38.5°C after half of the second unit has been transfused. What are the possible causes of the fever? What are the appropriate nursing interventions?

Assessment of Digestive and Gastrointestinal Function

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Describe the structure and function of the organs of the gastrointestinal tract.
2. Describe the mechanical and chemical processes involved in digesting and absorbing foods and eliminating waste products.
3. Use assessment parameters appropriate for determining the status of gastrointestinal function.
4. Describe the appropriate preparation, teaching, and follow-up care for patients who are undergoing diagnostic testing of the gastrointestinal tract.
Anatomic and Physiologic Overview

ANATOMY OF THE GASTROINTESTINAL TRACT

The GI tract is a 23- to 26-foot-long pathway that extends from the mouth through the esophagus, stomach, and intestines to the anus (Fig. 34-1). The esophagus is located in the mediastinum in the thoracic cavity, anterior to the spine and posterior to the trachea and heart. This collapsible tube, which is about 25 cm (10 inches) in length, becomes distended when food passes through it. It passes through the diaphragm at an opening called the diaphragmatic hiatus.

The remaining portion of the GI tract is located within the peritoneal cavity. The stomach is situated in the upper portion of the abdomen to the left of the midline, just under the diaphragm. It is a distensible pouch with a capacity of approximately 1500 mL. The inlet to the stomach is called the esophagogastric junction; it is surrounded by a ring of smooth muscle called the lower esophageal sphincter (or cardiac sphincter), which, on contraction, closes off the stomach from the esophagus. The stomach can be divided into four anatomic regions: the cardia (entrance), fundus, body, and pylorus (outlet). Circular smooth muscle in the wall of the pylorus forms the pyloric sphincter and controls the opening between the stomach and the small intestine.

The small intestine is the longest segment of the GI tract, accounting for about two thirds of the total length. It folds back and forth on itself, providing approximately 7000 cm of surface area for secretion and absorption, the process by which nutrients enter the bloodstream through the intestinal walls. The small intestine is divided into three anatomic parts: the upper part, called the duodenum; the middle part, called the jejunum; and the lower part, called the ileum. The common bile duct, which allows for the passage of both bile and pancreatic secretions, empties into the duodenum at the ampulla of Vater. The junction between the small and large intestine, the cecum, is located in the right lower portion of the abdomen. The ileocecal valve is located at this junction. It controls the passage of intestinal contents into the large intestine and prevents reflux of bacte-

Function of the Digestive System

All cells of the body require nutrients. These nutrients are derived from the intake of food that contains proteins, fats, carbohydrates, vitamins and minerals, and cellulose fibers and other vegetable matter of no nutritional value. The primary digestive functions of the GI tract are the following:

- To break down food particles into the molecular form for digestion

Glossary

absorption: phase of the digestive process that occurs when small molecules, vitamins, and minerals pass through the walls of the small and large intestine and into the bloodstream
amylase: an enzyme that aids in the digestion of starch
anus: last section of the GI tract; outlet for waste products from the system
chyme: mixture of food with saliva, salivary enzymes, and gastric secretions that is produced as the food passes through the mouth, esophagus, and stomach
digestion: phase of the digestive process that occurs when digestive enzymes and secretions mix with ingested food and when proteins, fats, and sugars are broken down into their component smaller molecules
elimination: phase of digestive process that occurs after digestion and absorption, when waste products are evacuated from the body
esophagus: collapsible tube connecting the mouth to the stomach, through which food passes as it is ingested
fibroscopy (gastrointestinal): intubation of a part of the GI system with a flexible, lighted tube to assist in diagnosis and treatment of diseases of that area
hydrochloric acid: acid secreted by the glands in the stomach; mixes with chyme to break it down into absorbable molecules and aid in the destruction of bacteria
ingestion: phase of the digestive process that occurs when food is taken into the GI tract via the mouth and esophagus
intrinsic factor: a gastric secretion that combines with vitamin B12 so that the vitamin can be absorbed
large intestine: the portion of the GI tract into which waste material from the small intestine passes as absorption continues and elimination begins; consists of several parts—ascending segment, transverse segment, descending segment, sigmoid colon, and rectum
lipase: an enzyme that aids in the digestion of fats
mouth: first portion of the GI tract, through which food is ingested
pepsin: a gastric enzyme that is important in protein digestion
small intestine: longest portion of the GI tract, consisting of three parts—duodenum, jejunum, and ileum—through which food mixed with all secretions and enzymes passes as it continues to be digested and begins to be absorbed into the bloodstream
stomach: distensible pouch into which the food bolus passes to be digested by gastric enzymes
trypsin: enzyme that aids in the digestion of protein
• To absorb into the bloodstream the small molecules produced by digestion
• To eliminate undigested and unabsorbed foodstuffs and other waste products from the body

After food is ingested, it is propelled through the GI tract, coming into contact with a wide variety of secretions that aid in its digestion, absorption, or elimination from the GI tract.

**Chewing and Swallowing**

The process of digestion begins with the act of chewing, in which food is broken down into small particles that can be swallowed and mixed with digestive enzymes. Eating—or even the sight, smell, or taste of food—can cause reflex salivation. Saliva is secreted from three pairs of glands: the parotid, the submaxillary, and the sublingual glands. Approximately 1.5 L of saliva is secreted daily. Saliva is the first secretion that comes in contact with food. Saliva contains the enzyme ptyalin, or salivary amylase, which begins the digestion of starches (Table 34-1). Saliva also contains mucus and water, which help to lubricate the food as it is chewed, thereby facilitating swallowing.

Swallowing begins as a voluntary act that is regulated by a swallowing center in the medulla oblongata of the central nervous system. As food is swallowed, the epiglottis moves to cover the tracheal opening and prevent aspiration of food into the lungs. Swallowing, which propels the bolus of food into the upper esophagus, thus ends as a reflex action. The smooth muscle in the wall of the esophagus contracts in a rhythmic sequence from the upper esophagus toward the stomach to propel the bolus of food along the tract. During this process of esophageal peristalsis, the lower esophageal sphincter relaxes and permits the bolus of food to enter the stomach. Subsequently, the lower esophageal sphincter closes tightly to prevent reflux of stomach contents into the esophagus.
Gastric Function

The stomach stores and mixes the food with secretions. It secretes a highly acidic fluid in response to the presence or anticipated ingestion of food. This fluid, which may have a pH as low as 1, derives its acidity from the hydrochloric acid (HCl) secreted by the glands of the stomach. The function of this gastric secretion is two-fold: to break down food into more absorbable components and to aid in the destruction of most ingested bacteria. The stomach can produce about 2.4 L per day of these gastric secretions. Gastric secretions also contain the enzyme pepsin, which is important for initiating protein digestion. Intrinsic factor is also secreted by the gastric mucosa. This compound combines with dietary vitamin B₁₂ so that the vitamin can be absorbed in the ileum. In the absence of intrinsic factor, vitamin B₁₂ cannot be absorbed and pernicious anemia results (see Chapter 33).

Peristaltic contractions in the stomach propel its contents toward the pylorus. Because large food particles cannot pass through the pyloric sphincter, they are churned back into the body of the stomach. In this way, food in the stomach is agitated mechanically and broken down into smaller particles. Food remains in the stomach for a variable length of time, from a half-hour to several hours, depending on the size of food particles, the composition of the meal, and other factors. Peristalsis in the stomach and contractions of the pyloric sphincter allow the partially digested food to enter the small intestine at a rate that permits efficient absorption of nutrients. This food mixed with gastric secretions is called chyme. Hormones, neuroregulators, and local regulators found in the gastric secretions control the rate of gastric secretions and influence gastric motility (Table 34-2).

Small Intestine Function

The digestive process continues in the duodenum. Secretions in the duodenum come from the accessory digestive organs—the pancreas, liver, and gallbladder—and the glands in the wall of the intestine itself. These secretions contain digestive enzymes and bile. Pancreatic secretions have an alkaline pH because of high concentrations of bicarbonate. This neutralizes the acid entering the duodenum from the stomach. The pancreas also secretes digestive enzymes, including trypsin, which aids in digesting protein; amylase, which aids in digesting starch; and lipase, which

Aids in digesting fats. Bile (secreted by the liver and stored in the gallbladder) aids in emulsifying ingested fats, making them easier to digest and absorb.

The intestinal glands secrete mucus, hormones, electrolytes, and enzymes. The mucus coats the cells and protects the mucosa from injury by HCl. Hormones, neuroregulators, and local regulators found in these intestinal secretions control the rate of intestinal secretions and also influence GI motility. Intestinal secretions total approximately 1 L/day of pancreatic juice, 0.5 L/day of bile, and 3 L/day of secretions from the glands of the small intestine. Tables 34-1 and 34-2 summarize the actions of digestive enzymes and GI regulatory substances.

Two types of contractions occur regularly in the small intestine: segmentation contractions and intestinal peristalsis. Segmentation contractions produce mixing waves that move the intestinal contents back and forth in a churning motion. Intestinal peristalsis propels the contents of the small intestine toward the colon. Both movements are stimulated by the presence of chyme.

Food, initially ingested in the form of fats, proteins, and carbohydrates, is broken down into absorbable particles (constituent nutrients) by the process of digestion. Carbohydrates are broken down into disaccharides (eg, sucrose, maltose, galactose) and monosaccharides (eg, glucose, fructose). Glucose is the major carbohydrate that the tissue cells use as fuel. Proteins are broken down into amino acids and peptides. Ingested fats are emulsified into monoglycerides and fatty acids. These smaller molecules are then ready to be absorbed. Chyme stays in the small intestine for 3 to 6 hours, allowing for continued breakdown and absorption of nutrients.

Small, finger-like projections called villi are present throughout the entire intestine and function to produce digestive enzymes as well as to absorb nutrients. Absorption is the primary function of the small intestine. Vitamins and minerals are not digested but rather absorbed essentially unchanged. Absorption begins in the jejunum and is accomplished by both active transport and diffusion across the intestinal wall into the circulation. Absorption of different nutrients takes place at different locations in the small intestine. Iron and calcium absorption takes place in the duodenum. Fats, proteins, carbohydrates, sodium, and chloride are absorbed in the jejunum. Vitamin B₁₂ and bile salts are absorbed in the ileum. Magnesium, phosphate, and potassium are absorbed throughout the small intestine (Society of Gastroenterologic Nursing and Associates, 1998).

### Colonic Function

Within 4 hours after eating, residual waste material passes into the terminal ileum and passes slowly into the proximal portion of the colon through the ileocecal valve. This valve, which is normally closed, helps prevent colonic contents from refluxing into the small intestine. With each peristaltic wave of the small intestine, the valve opens briefly and permits some of the contents to pass into the colon.

Bacteria make up a major component of the contents of the large intestine. They assist in completing the breakdown of waste material, especially of undigested or unabsorbed proteins and bile salts. Two types of colonic secretions are added to the residual material: an electrolyte solution and mucus. The electrolyte solution is chiefly a bicarbonate solution that acts to neutralize the end products formed by the colonic bacterial action. The mucus protects the colonic mucosa from the interluminal contents and also provides adherence for the fecal mass.
Slow, weak peristaltic activity moves the colonic contents slowly along the tract. This slow transport allows efficient reabsorption of water and electrolytes, which is the primary purpose of the colon. Intermittent strong peristaltic waves propel the contents for considerable distances. This generally occurs after another meal is eaten, when intestine-stimulating hormones are released. The waste materials from a meal eventually reach and distend the rectum, usually in about 12 hours. As much as one fourth of the waste materials from a meal may still be in the rectum 3 days after the meal was ingested.

**Waste Products of Digestion**

Feces consist of undigested foodstuffs, inorganic materials, water, and bacteria. Fecal matter is about 75% fluid and 25% solid material. The composition is relatively unaffected by alterations in diet, because a large portion of the fecal mass is of nondietary origin, derived from the secretions of the GI tract. The brown color of the feces results from the breakdown of bile by the intestinal bacteria. Chemicals formed by intestinal bacteria (especially indole and skatole) are responsible in large part for the fecal odor. Gases formed contain methane, hydrogen sulfide, and ammonia, among others. The GI tract normally contains approximately 150 mL of these gases, which are either absorbed into the portal circulation and detoxified by the liver or expelled from the rectum as flatus.

Elimination of stool begins with distention of the rectum, which reflexively initiates contractions of the rectal musculature and relaxes the normally closed internal anal sphincter. The internal sphincter is controlled by the autonomic nervous system; the external sphincter is under the conscious control of the cerebral cortex. During defecation, the external anal sphincter voluntarily relaxes to allow colonic contents to be expelled. Normally, the external anal sphincter is maintained in a state of tonic contraction. Thus, defecation is seen to be a spinal reflex (involving the parasympathetic nerve fibers) that can be inhibited voluntarily by keeping the external anal sphincter closed. Contracting the abdominal muscles (straining) facilitates emptying of the colon. The average frequency of defecation in humans is once daily, but the frequency varies among individuals.

Assessment

**HEALTH HISTORY AND CLINICAL MANIFESTATIONS**

The nurse begins by taking a complete history, focusing on symptoms common to GI dysfunction. These symptoms include pain, indigestion, intestinal gas, nausea and vomiting, hematemesis, and changes in bowel habits and stool characteristics. Information about any previous GI disease is important. The nurse notes past and current medication use and any previous treatment or surgery. Information pertaining to medications is of particular interest because medications are a frequent cause of GI symptoms. The nurse takes a dietary history to assess nutritional status. Questioning about the use of tobacco and alcohol includes details about type and amount. The nurse and patient discuss changes in appetite or eating patterns and any examples of unexplained weight gain or loss over the past year. The nurse also assesses the stool characteristics. The nurse records all abnormal findings and reports them to the physician. It is important to include in the history questions about psychosocial, spiritual, or cultural factors that may be affecting the patient.

**Pain**

Pain can be a major symptom of GI disease. The character, duration, pattern, frequency, location, distribution of referred pain (Fig. 34-3), and time of the pain vary greatly depending on the underlying cause. Other factors, such as meals, rest, defecation, and vascular disorders, may directly affect this pain.

**Indigestion**

Upper abdominal discomfort or distress associated with eating (commonly called indigestion) is the most common symptom of patients with GI dysfunction. The basis for this abdominal distress may be the patient’s own gastric peristaltic movements. Bowel movements may or may not relieve the pain. Indigestion can result from disturbed nervous system control of the stomach.

![FIGURE 34-3 Common sites of referred abdominal pain.](image)
or from a disorder in the GI tract or elsewhere in the body. Fatty foods tend to cause the most discomfort, because they remain in the stomach longer than proteins or carbohydrates do. Coarse vegetables and highly seasoned foods can also cause considerable distress.

**Intestinal Gas**

The accumulation of gas in the GI tract may result in belching (the expulsion of gas from the stomach through the mouth) or flatulence (the expulsion of gas from the rectum). It is through belching that swallowed air is expelled quickly when it reaches the stomach. Usually, gases in the small intestine pass into the colon and are released as flatus. Patients often complain of bloating, distention, or being “full of gas.” Excessive flatulence may be a symptom of gallbladder disease or food intolerance.

**Nausea and Vomiting**

Vomiting is another major symptom of GI disease. Vomiting is usually preceded by nausea, which can be triggered by odors, activity, or food intake. The emesis, or vomitus, may vary in color and content. It may contain undigested food particles or blood (hematemesis). When vomiting occurs soon after hemorrhage, the emesis is bright red. If blood has been retained in the stomach, it takes on a coffee-ground appearance because of the action of the digestive enzymes.

**Change in Bowel Habits and Stool Characteristics**

Changes in bowel habits may signal colon disease. Diarrhea (an abnormal increase in the frequency and liquidity of the stool or in daily stool weight or volume) commonly occurs when the contents move so rapidly through the intestine and colon that there is inadequate time for the GI secretions to be absorbed. Diarrhea is sometimes associated with abdominal pain or cramping and nausea or vomiting. Constipation (a decrease in the frequency of stool, or stools that are hard, dry, and of smaller volume than normal) may be associated with anal discomfort and rectal bleeding. See Chapter 38 for further discussion of diarrhea and constipation.

The characteristics of the stool can vary greatly. Stool is normally light to dark brown. However, many circumstances, including the ingestion of certain foods and medications, can change the appearance of stool (Table 34-3). Blood in the stool can present in various ways and must be investigated. If blood is shed in sufficient quantities into the upper GI tract, it produces a tarry-black color (melena). Blood entering the lower portion of the GI tract or passing rapidly through it will appear bright or dark red. Lower rectal or anal bleeding is suspected if there is streaking of blood on the surface of the stool or if blood is noted on toilet tissue. Other common abnormalities in stool characteristics that the patient may describe during the health history include the following:

- Bulky, greasy, foamy stools that are foul in odor; stool color is gray, with a silvery sheen
- Light gray or clay-colored stool, caused by the absence of urobilin
- Stool with mucus threads or pus that may be visible on gross inspection of the stool
- Small, dry, rock-hard masses called scybala; sometimes streaked with blood from rectal trauma as they pass through the rectum
- Loose, watery stool that may or may not be streaked with blood

**PHYSICAL ASSESSMENT**

The physical examination includes assessment of the mouth, abdomen, and rectum. The mouth, tongue, buccal mucosa, teeth, and gums are inspected, and ulcers, nodules, swelling, discoloration, and inflammation are noted. People with dentures should remove them during this part of the examination to allow good visualization.

The patient lies supine with knees flexed slightly for inspection, auscultation, palpation, and percussion of the abdomen (Fig. 34-4). The nurse performs inspection first, noting skin changes and scars from previous surgery. It is also important to note the contour and symmetry of the abdomen, to identify any localized bulging, distention, or peristaltic waves.

The nurse performs auscultation before percussion and palpation (which can increase intestinal motility and thereby change bowel sounds) and notes the character, location, and frequency of bowel sounds. The nurse assesses bowel sounds in all four quadrants using the diaphragm of the stethoscope; the high-pitched and gurgling sounds can be heard best in this manner. It is important to document the frequency of the sounds, using the terms normal (sounds heard about every 5 to 20 seconds), hypoactive (one or two sounds in 2 minutes), hyperactive (5 to 6 sounds heard in less than 30 seconds), or absent (no sounds in 3 to 5 minutes).

The nurse notes tympany or dullness during percussion. Use of light palpation is appropriate for identifying areas of tenderness or swelling; the nurse may use deep palpation to identify masses in any of the four quadrants. If the patient identifies any area of discomfort, the nurse can assess for rebound tenderness. To elicit rebound tenderness, the nurse exerts pressure over the area and then releases it quickly. It is important to note any pain experienced on withdrawal of the pressure. The nurse notes any abnormal finding in relation to the surface landmarks (xiphoid process, costal margins, anterior iliac spine, and symphysis pubis) or in relation to the four quadrants commonly used to describe the abdomen (right upper quadrant, RUQ; right lower quadrant, RLQ; left upper quadrant, LUQ; and left lower quadrant, LLQ) (Bickley & Hoekelman, 1999).

The final part of the examination is inspection of the anal and perineal area. The nurse should inspect and palpate areas of excoriation or rash, fissures or fistula openings, or external hemorrhoids. A digital rectal examination can be performed to note any areas of tenderness or mass.
Diagnostic Evaluation

Blood tests are ordered initially. Common blood tests include complete blood count (CBC), carcinoembryonic antigen (CEA), liver function tests, serum cholesterol, and triglycerides. Test findings may reveal alterations in basal metabolic function and may indicate the severity of a disorder.

Many other modalities are available for diagnostic assessment of the GI tract. The majority of these tests and procedures are performed on an outpatient basis in special units designed for this purpose (e.g., endoscopy or GI laboratory). The nurse supports and educates patients who are undergoing diagnostic evaluation, whether in an inpatient or an outpatient setting. Patients who require such tests frequently are anxious, elderly, or debilitated. The preparation for many of these studies includes fasting, the use of laxatives or enemas, and ingestion or injection of a contrast agent or a radiopaque dye. These preparatory measures are poorly tolerated by weak and many elderly patients and have the potential to cause fluid and electrolyte imbalances. If further assessment or treatment is needed after any outpatient procedure, the patient may be admitted to the hospital.

Specific nursing interventions for each test are provided later in this chapter. General nursing interventions for the patient who is having GI diagnostic assessment include the following:

- Providing general information about a healthy diet and the nutritional factors that can cause GI disturbances; after a diagnosis has been confirmed, the nurse provides information about specific nutrients that should be included in the diet
- Providing needed information about the test and the activities required of the patient
- Providing instructions about postprocedure care and activity restrictions
- Alleviating anxiety
- Helping the patient cope with discomfort
- Encouraging family members or others to offer emotional support to the patient during the diagnostic testing
- Assessing for adequate hydration before, during, and immediately after the procedure, and providing education about maintenance of hydration

STOOL TESTS

Basic examination of the stool includes inspecting the specimen for consistency and color and testing for occult (not visible) blood. Special tests, including tests for fecal urobilinogen, fat, nitrogen, parasites, pathogens, food residues, and other substances, require that the specimen be sent to the laboratory.

Stool samples are usually collected on a random basis unless a quantitative study (e.g., fecal fat, urobilinogen) is to be performed. Random specimens should be sent promptly to the laboratory for analysis. The quantitative 24- to 72-hour collections must be kept refrigerated until they are taken to the laboratory. Some stool collections require the patient to follow a special diet or to refrain from taking certain medications before the collection. It is important to follow test guidelines closely for accurate results.

Fecal occult blood testing is one of the most commonly performed stool tests. It can be useful in initial screening for several
disorders. It tests only for the presence of blood, so other follow-up testing is required. It is most frequently used in cancer screening programs and for early cancer detection (Chart 34-1). The test can be performed at the bedside, in the laboratory, or at home. It tests for heme, the iron-containing portion of the hemoglobin molecule that is altered during transit through the intestines. 

Probably the most widely used occult blood test is the Hema-test. It is inexpensive and noninvasive, and it carries no risk to the patient. It should not, however, be performed when there is hemorrhoidal bleeding. The test can be performed at home as well as in the doctor’s office. The patient provides a stool specimen, and the physician smears it on a dry, guaiac-impregnated paper slide. If the test is done at home, the patient mails the slide to the physician in an envelope provided for that purpose. The stool specimen is then examined for occult blood. Serial 3- to 6-day testing is recommended. The test is not perfect, because certain factors interfere with its sensitivity and specificity. False-positive results may occur if the patient has eaten rare meat, liver, poultry, turnips, broccoli, cauliflower, melons, salmon, sardines, or horseradish within 7 days before testing. Medications that can cause gastric irritation, such as aspirin, ibuprofen, indomethacin, colchicine, corticosteroids, cancer chemotherapeutic agents, and anticoagulants, may also cause false-positive results. Extensive research has demonstrated that therapeutic doses of iron preparations do not cause false-positive results. Ingestion of vitamin C from supplements or foods can cause false-negative results. Therefore, a careful assessment of the patient’s diet and medication regimen is essential to reduce incorrect interpretation of results (Ahmed, 2000).

Other occult blood tests that may yield more specific and more sensitive readings include Hematest II SENSA and HemoQuant. Immunologic tests are more specific to human hemoglobin and decrease the problem of dietary interference. Hemoporphyrin assay detects the broadest range of blood derivatives, but a strict dietary protocol is essential. Immunoochemical tests using anti-human antibodies that are extremely sensitive to human hemoglobin are also available.

**BREATHE TESTS**

The hydrogen breath test was developed to evaluate carbohydrate absorption. It also is used to aid in the diagnosis of bacterial overgrowth in the intestine and short bowel syndrome. This test determines the amount of hydrogen expelled in the breath after it has been produced in the colon (on contact of galactose with fermenting bacteria) and absorbed into the blood. 

Urea breath tests detect the presence of Helicobacter pylori, the bacteria that can live in the mucosal lining of the stomach and cause peptic ulcer disease. The patient takes a capsule of carbon-labeled urea and then provides a breath sample 10 to 20 minutes later. Because H. pylori metabolizes urea rapidly, the labeled carbon is absorbed quickly; it can then be measured as carbon dioxide in the expired breath to determine whether H. pylori is present. The patient is instructed to avoid antibiotics or loperamide (Pepto-Bismol) for 1 month before the test; sucralfate (Carafate) and omeprazole (Prilosec) for 1 week before the test; and cimetidine (Tagamet), famotidine (Pepcid), ranitidine (Zantac), and nizatidine (Axid) for 24 hours before urea breath testing. H. pylori also can be detected by assessing serum antibody levels.

**ABDOMINAL ULTRASOUNOGRAPHY**

Ultrasonography is a noninvasive diagnostic technique in which high-frequency sound waves are passed into internal body structures and the ultrasonic echoes are recorded on an oscilloscope as they strike tissues of different densities. During abdominal ultrasonography, an image of the abdominal organs and structures is produced on the oscilloscope. This procedure is generally used to indicate the size and configuration of abdominal structures. It is particularly useful in the detection of cholelithiasis, cholecystitis, and appendicitis. Most recently this technique has proven useful in diagnosing acute colonic diverticulitis.

Advantages of abdominal ultrasonography are that it requires no ionizing radiation, there are no noticeable side effects, and it is relatively inexpensive. One disadvantage is that it cannot be used to examine structures that lie behind bony tissue, because bone prevents sound waves from passing to deeper structures. Gas and fluid in the abdomen or air in the lungs also prevent transmission of ultrasound.

Endoscopic ultrasonography (EUS) is a specialized enteroscopic procedure that aids in the diagnosis of GI disorders by providing direct imaging of a target area. A small high-frequency ultrasonic transducer is mounted at the tip of the fiberoptic scope so that a transintestinal study can be completed. This procedure gives results with better quality resolution and definition than regular ultrasound imaging. It helps in staging of a tumor, including size, spread, and whether the tumor is operable. It is useful in evaluating transmural changes in the bowel wall that occur in ulcerative colitis. Intestinal gas, bone, and thick layers of adipose tissue (all of which hamper conventional ultrasonography) are not problems when this technique is used.

**Nursing Interventions**

The patient fasts for 8 to 12 hours before the test to decrease the amount of gas in the bowel. If gallbladder studies are being performed, the patient should eat a fat-free meal the evening before...
Inquire whether any affected family member has had DNA management issues specific to genetics with familial adenomatous polyposis—congenital hypertrrophic pyloric stenosis

Assess for other family members in several generations with inflammatory bowel disease (eg, Crohn’s disease) or hereditary nonpolyposis colorectal cancer (HNPCC)

Assess for presence of other clinical symptoms:

With clefting—congenital heart defect, mental retardation, other birth defects suggestive of a genetic syndrome

With familial adenomatous polyposis—congenital hypertrophy of retinal pigment epithelium (CHRPE)

If indicated, refer for further genetic counseling and evaluation so that family members can discuss inheritance, risk to other family members, availability of genetic testing, and gene-based interventions

Offer appropriate genetics information and resources

Assess patients’ understanding of genetics information

Provide support to families with newly diagnosed genetics-related digestive disorders

Participate in management and coordination of care for patients with genetic conditions and for those who are predisposed to develop or pass on a genetic condition

DNA TESTING

Researchers have refined methods for genetic risk assessment, preclinical diagnosis, and prenatal diagnosis to identify persons who are at risk for certain GI disorders (eg, gastric cancer, lactose deficiency, inflammatory bowel disease, colon cancer). In some cases, DNA testing allows practitioners to prevent (or minimize) disease, by intervening before its onset, and to improve therapy. Persons who are identified as at risk for certain GI disorders may choose to undergo genetic counseling to learn about the disease; to understand options for preventing and treating the disease; and to receive support in coping with the situation (Yamada, 1999).

Persons at risk for colon cancer often are targeted for DNA testing because it can provide a head start on this preventable cancer.

IMAGING STUDIES

Imaging studies include x-ray and contrast studies, computed tomography (CT) scans, magnetic resonance imaging (MRI), and scintigraphy (radionuclide imaging).

Upper Gastrointestinal Tract Study

X-rays can delineate the entire GI tract after the introduction of a contrast agent. A radiopaque liquid (eg, barium sulfate) is commonly used. The patient ingests this tasteless, odorless, nongranular, and completely insoluble (hence, not absorbable) powder in the form of a thick or thin aqueous suspension for the purpose of studying the upper GI tract (upper GI series or barium swallow). The upper GI series enables the examiner to detect or exclude anatomic or functional derangement of the upper GI organs or sphincters. It also aids in the diagnosis of ulcers, varices, tumors, regional enteritis, and malabsorption syndromes. The procedure may be extended to examine the duodenum and small bowel (small bowel follow-through).

The patient swallows barium under direct fluoroscopic examination. As the barium descends into the stomach, the position, patency, and caliber of the esophagus are visualized, enabling the examiner to detect or exclude any anatomic or functional derangement of that organ. Fluoroscopic examination next extends to the stomach as its lumen fills with barium, allowing observation of stomach motility, thickness of the gastric wall, the mucosal pattern, patency of the pyloric valve, and the anatomy of the duodenum. Multiple x-ray films are obtained during the procedure, and additional images may be taken at intervals for up to 10 minutes.
24 hours to evaluate the rate of gastric emptying. Small bowel x-rays taken while the barium is passing through that area allow for observation of the motility of the small bowel. Obstructions, ileitis, and diverticula can be detected if present.

Variations of the upper GI study include double-contrast studies and enteroclysis. The double-contrast method of examining the upper GI tract involves administration of a thick barium suspension to outline the stomach and esophageal wall, after which tablets that release carbon dioxide in the presence of water are given. This technique has the advantage of showing the esophagus and stomach in finer detail, permitting signs of early superficial neoplasms to be noted.

Enteroclysis is a very detailed, double-contrast study of the entire small intestine that involves the continuous infusion, through a duodenal tube, of 500 to 1000 mL of a thin barium sulfate suspension. Methylcellulose is then infused into the small intestine through the tube. The barium and methylcellulose fill the intestinal loops and are observed continuously by fluoroscopy and viewed at frequent intervals as they progress through the jejunum and the ileum. This process (even with normal motility) can take up to 6 hours. The procedure aids in the diagnosis of partial small-bowel obstructions or diverticula.

**NURSING INTERVENTIONS**

The patient may need to maintain a low-residue diet for several days before the test. He or she should receive nothing by mouth after midnight before the test. The physician may prescribe a laxative to clean out the intestinal tract. Because smoking can stimulate gastric motility, the nurse discourages the patient from smoking on the morning before the examination. In addition, the nurse withholds all medications.

Follow-up care is needed after any of the upper GI procedures to ensure that the patient has completely eliminated the ingested barium. Fluids must be increased to facilitate evacuation of stool and barium. The nurse monitors the patient’s stools until they return to their normal color (the barium will look like clay). A laxative or enema may be needed.

**Lower Gastrointestinal Tract Study**

When barium is instilled rectally to visualize the lower GI tract, the procedure is called a barium enema. The purpose of a barium enema is to detect the presence of polyps, tumors, and other lesions of the large intestine and to demonstrate any abnormal anatomy or malfunction of the bowel.

The radiopaque substance is instilled rectally in the radiology department during fluoroscopy. If the patient has been prepared adequately and the colon has been evacuated completely, the contour of the entire colon, including the cecum and appendix (if patent), is clearly visible and the motility of each portion may be observed readily. The procedure usually takes about 15 to 30 minutes, during which time x-ray images are taken.

Other means for visualizing the colon include double-contrast studies and a water-soluble contrast study. A double-contrast or air-contrast barium enema involves the instillation of a thicker barium solution, followed by the instillation of air. The patient may feel some cramping or discomfort with this process. This test provides a contrast between the air-filled lumen and the barium-coated mucosa, allowing easier detection of smaller lesions.

If active inflammatory disease, fistulas, or perforation of the colon is suspected, a water-soluble iodinated contrast agent (eg, Gastrografin) can be used. The procedure is the same as for a barium enema; however, the patient must be assessed for allergy to iodine or contrast agent. The contrast agent is eliminated readily after the procedure, so there is no need for postprocedure laxatives. Some diarrhea may occur in a few patients until the contrast agent has been totally eliminated.

**NURSING INTERVENTIONS**

Preparing the patient includes emptying and cleansing the lower bowel. This often necessitates a low-residue diet 1 to 2 days before the test (the preparation required by different radiology departments may vary); a clear liquid diet and a laxative the evening before; nothing by mouth after midnight; and cleansing enemas until returns are clear the following morning. The nurse should make sure that barium enemas are scheduled before any upper GI studies. If the patient has active inflammatory disease of the colon, enemas are contraindicated. Barium enema also is contraindicated in patients with signs of perforation or obstruction; instead, a water-soluble contrast study may be performed in these situations. Active GI bleeding may prohibit the use of laxatives and enemas.

The nurse administers an enema or laxative after these tests to facilitate barium removal. Increasing fluid intake will assist in eliminating the barium. As with any barium study, the nurse monitors the patient for complete elimination of the barium.

**Computed Tomography**

CT provides cross-sectional images of abdominal organs and structures. Multiple x-ray images are taken from many different angles, digitized in the computer, reconstructed, and then viewed on a computer monitor. Indications for abdominal CT scanning are diseases of the liver, spleen, kidney, pancreas, and pelvic organs. CT is a valuable tool for detecting and localizing many inflammatory conditions in the colon, such as appendicitis, diverticulitis, regional enteritis, and ulcerative colitis. Because the adequacy of detail in the test depends on the presence of fat, this diagnostic tool is not useful for very thin, cachectic patients. The procedure is completely painless, but radiation doses are considerable. Because a scanning time of 5 seconds is required, motion artifacts produced by heartbeat and respiration cannot be avoided, resulting in pictures that are less than clear.

New, continuous-motion (helical or spiral), three-dimensional CT scans have been developed that provide very detailed pictures of the GI organs and vasculature (Yamada, 1999). Colonography can be completed in minutes. It involves inserting a thin, straw-like tube into the colon and inflating the bowel with air to generate a computer image of the intestine. There is little discomfort, and sedation is not needed.

**NURSING INTERVENTIONS**

The patient should not eat or drink for 6 to 8 hours before the test. The practitioner may prescribe an intravenous or oral contrast agent. Therefore, the nurse should question the patient about contrast dye allergies. If barium studies are to be performed, it is important to schedule them after CT scanning, so as not to interfere with imaging.

**Magnetic Resonance Imaging**

MRI is used in gastroenterology to supplement ultrasonography and CT scanning. It is a noninvasive technique that uses magnetic fields and radio waves to produce an image of the area being
studied. The use of oral contrast agents to enhance the image has increased the application of this technique for the diagnosis of GI diseases. It is useful in evaluating abdominal soft tissues as well as blood vessels, abscesses, fistulas, neoplasms, and other sources of bleeding.

The physiologic artifacts of heartbeat, respiration, and peristalsis may create a less-than-clear image. Newer, fast-imaging MRI techniques help to eliminate these physiologic motion artifacts. MRI is contraindicated for patients with permanent pacemakers, artificial heart valves and defibrillators, implanted insulin pumps, or implanted transcutaneous electrical nerve stimulation devices, because the magnetic field could cause malfunction. MRI is also contraindicated for patients with internal metal devices (eg, aneurysm clips) or intraocular metallic fragments.

**NURSING INTERVENTIONS**
The patient should not eat or drink for 6 to 8 hours before the test. Before the test, the patient must remove all jewelry and other metals. The patient lies in a machine that constructs an image based on the magnetic field created between the machine and the structures scanned. The entire procedure takes 30 to 90 minutes.

It is important to warn patients that the close-fitting scanners used in many MRI facilities may induce feelings of claustrophobia and that the machine will make a knocking sound during the procedure. Open MRIs that are less close-fitting eliminate the claustrophobia that many patients experience.

**Scintigraphy**
Scintigraphy (radionuclide testing) relies on the use of radioactive isotopes (ie, technetium, iodine, and indium) to reveal displaced anatomic structures, changes in organ size, and the presence of neoplasms or other focal lesions, such as cysts or abscesses.

Scintigraphic scanning is also used to measure the uptake of tagged red blood cells and leukocytes. Tagging of red blood cells and leukocytes by injection of a radionuclide is performed to define areas of inflammation, abscess, blood loss, or neoplasm. A sample of blood is removed, mixed with a radioactive substance, and reinjected into the patient. Abnormal concentrations of blood cells are then detected at 24- and 48-hour intervals.

**Gastrointestinal Motility Studies**
Radionuclide testing also is used to assess gastric emptying and colonic transit time. For gastric emptying studies, the liquid and solid components of a meal are tagged with radionuclide markers. After the patient ingests the meal, the patient is positioned under a scintiscanner, which measures the rate of passage of the radioactive substance out of the stomach. This is useful in diagnosing disorders of gastric motility. Radionuclide evaluation of gastric emptying is now preferred over intubation methods because it gives more defined results (Phillips & Wingate, 1998). This procedure is helpful for evaluating any functional cause of gastric emptying, but its most common clinical uses at this time are in the evaluation of diabetic gastroparesis and of the rapid emptying process in the dumping syndrome.

Colonic transit studies are used to evaluate colonic motility instances of chronic constipation and obstructive defecation syndromes. This is usually an outpatient study. The patient is given a capsule containing 20 radionuclide markers and instructions to follow a regular diet and normal daily activities. Abdominal x-rays are taken every 24 hours until all markers are passed. This process usually takes 4 to 5 days, but in the presence of severe constipation it may take as long as 10 days. People with chronic diarrhea may be evaluated at 8-hour intervals. The amount of time it takes for the radioactive material to move through the colon indicates colonic motility.

**ENDOSCOPIC PROCEDURES**
Endoscopic procedures used in GI tract assessment include fibroscopy/esophagogastroduodenoscopy, anoscopy, proctoscopy, sigmoidoscopy, colonoscopy, small-bowel enteroscopy, and endoscopy through ostomy.

**Upper Gastrointestinal Fibroscopy/Esophagogastroduodenoscopy**
Fiberscopes are flexible scopes equipped with fiberoptic lenses. **Fibroscopy** of the upper GI tract allows direct visualization of the esophageal, gastric, and duodenal mucosa through a lighted endoscope (gastroscope) (Fig. 34-5). This procedure,
called esophagogastroduodenoscopy (EGD), is especially valuable when esophageal, gastric, or duodenal abnormalities or inflammatory, neoplastic, or infectious processes are suspected. This procedure also can be used to evaluate esophageal and gastric motility and to collect secretions and tissue specimens for further analysis.

The gastroenterologist views the GI tract through a viewing lens and can take still or video photographs through the scope to document findings. Electronic video endoscopes also are available that attach directly to a video processor, converting the electronic signals into pictures on a television screen. This allows larger and continuous viewing capabilities, as well as the simultaneous recording of the procedure.

Side-viewing flexible scopes are used to visualize the common bile duct and the pancreatic and hepatic ducts through the ampulla of Vater in the duodenum. This procedure, called endoscopic retrograde cholangiopancreatography (ERCP), uses the endoscope in combination with radiographic techniques to view the ductal structures of the biliary tract. ERCP is helpful in evaluating jaundice, pancreatitis, pancreatic tumors, common duct stones, and biliary tract disease. ERCP is described further in Chapter 40.

Upper GI fibroscopy also can be a therapeutic procedure when it is combined with other procedures. Therapeutic endoscopy can be used to remove common bile duct stones, dilate strictures, and treat gastric bleeding and esophageal varices. Laser-compatible scopes can be used to provide laser therapy for upper GI neoplasms. Sclerosing solutions can be injected through the scope in an attempt to control upper GI bleeding.

After the patient is sedated, the endoscope is lubricated with a water-soluble lubricant and passed smoothly and slowly along the back of the mouth and down into the esophagus. The gastroenterologist views the gastric wall and the sphincters, and then advances the endoscope into the duodenum for further examination. Biopsy forceps to obtain tissue specimens or cytology brushes to obtain cells for microscopic study can be passed through the scope. The procedure usually takes about 30 minutes.

The patient may experience nausea, gagging, or choking. Use of topical anesthetics and moderate sedation makes it important to monitor and maintain the oral airway during and after the procedure. Finger or ear oximeters are used to monitor oxygen saturation, and supplemental oxygen may be used if needed. Emergency equipment must be readily available. Precautions must be taken to protect the scope, because the fiberoptic bundles can be broken if the scope is bent at an acute angle. The patient wears a mouth guard to keep from biting the scope.

NURSING INTERVENTIONS

The patient should not eat or drink for 6 to 12 hours before the examination. Patient preparation includes helping the patient spray or gargle with a local anesthetic, and administering midazolam (Versed) intravenously just before the scope is introduced. Midazolam is a sedative that provides moderate sedation and relieves anxiety during the procedure. The nurse also may administer atropine to reduce secretions, and may give glucagon, if needed and prescribed, to relax smooth muscle. The nurse positions the patient on the left side to facilitate saliva drainage and to provide easy access for the endoscope. After the procedure, the nurse instructs the patient not to eat or drink until the gag reflex returns (in 1 to 2 hours), to prevent aspiration of food or fluids into the lungs. The nurse places the patient in the Sims position until he or she is awake and then places the patient in the semi-Fowler’s position until ready for discharge. After gastroscopy, assessment by the nurse includes observing for signs of perforation, such as pain, bleeding, unusual difficulty swallowing, and an elevated temperature. The nurse monitors the pulse and blood pressure for changes that can occur with sedation. The nurse can test the gag reflex by placing a tongue blade onto the back of the throat to see whether gagging occurs. After the patient’s gag reflex has returned, the nurse can offer lozenges, saline gargle, and oral analgesics to relieve minor throat discomfort. Patients who were sedated for the procedure must stay on bed rest until fully alert. After moderate sedation, the patient must be accompanied and transported home if the procedure was performed on an outpatient basis. The nurse instructs the patient not to drive for 10 to 12 hours if sedation was used.

Anoscopy, Proctoscopy, and Sigmoidoscopy

The lower portion of the colon also can be viewed directly to evaluate rectal bleeding, acute or chronic diarrhea, or change in bowel patterns and to observe for ulceration, fissures, abscesses, tumors, polyps, or other pathologic processes. Rigid or flexible fiberoptic scopes can be used. The anoscope is a rigid scope that is used to examine the anus and lower rectum. Proctoscopes and sigmoidoscopes are rigid scopes that are used to inspect the rectum and the sigmoid colon.

Flexible scopes have largely replaced the rigid scopes for routine examinations. The flexible fiberoptic sigmoidoscope (Fig. 34-6) permits the colon to be examined up to 40 to 50 cm (16 to 20 inches) from the anus, much more than the 25 cm (10 inches) that can be visualized with the rigid sigmoidoscope. The flexible scope has many of the same capabilities as the scopes used for the upper GI study, including the use of still or video images to document findings.

For rigid scope procedures, the patient assumes the knee-chest position at the edge of the bed or the examining table. With the back inclined at about a 45-degree angle, the patient is properly positioned for the introduction of an anoscope, proctoscope, or FIGURE 34-6 Flexible fiberoptic sigmoidoscopy. The flexible scope is advanced past the proximal sigmoid and then into the descending colon.
sigmoidoscope. During the examination, it is important to keep the patient informed about the progress of the examination and to explain that the pressure exerted by the instrument will create the urge to have a bowel movement.

For flexible scope procedures, the patient assumes a comfortable position on the left side with the right leg bent and placed anteriorly. Again, it is important to keep the patient informed throughout the examination and to explain the sensations associated with the examination. Biopsies and polypectomies can be performed during this procedure. Biopsy is performed with small biting forceps introduced through the endoscope; one or more small pieces of tissue may be removed. If rectal or sigmoid polyps are present, they may be removed with a wire snare, which is used to grasp the pedicle, or stalk. An electrocoagulating current is then used to sever the polyp and prevent bleeding. It is extremely important that all excised tissue be placed immediately in moist gauze or in an appropriate receptacle, labeled correctly, and delivered without delay to the pathology laboratory for examination.

**NURSING INTERVENTIONS**

These examinations require only limited bowel preparation, including a warm tap water or Fleet’s enema until returns are clear. Dietary restrictions usually are not necessary, and sedation usually is not required. During the procedure, the nurse monitors vital signs, skin color and temperature, pain tolerance, and vagal response (Society of Gastroenterologic Nursing and Associates, 2000). After the procedure, the nurse monitors the patient for rectal bleeding and signs of intestinal perforation (ie, fever, rectal drainage, abdominal distention, and pain). On completion of the examination, the patient can resume regular activities and dietary practices.

**Fiberoptic Colonoscopy**

Direct visual inspection of the colon to the cecum is possible by means of a flexible fiberoptic colonoscope (Fig. 34-7). These scopes have the same capabilities as those used for esophagogastro-duodenoscopy; however, they are larger in diameter and longer. Still and video recordings can be used to document the procedure and findings.

This procedure is used commonly as a diagnostic aid and screening device. It is most frequently used for cancer screening (see Chart 34-1) and for surveillance in patients with previous colon cancer or polyps. In addition, tissue biopsies can be obtained as needed, and polyps can be removed and evaluated. Other uses of colonoscopy include the evaluation of patients with diarrhea of unknown cause, occult bleeding, or anemia; further study of abnormalities detected on barium enema; and diagnosis, clarification, and determination of the extent of inflammatory or other bowel disease.

Therapeutically, the procedure can be used to remove all visible polyps with a special snare and cautery through the colonoscope. Many colon cancers begin with adenomatous polyps of the colon; therefore, one goal of colonoscopic polypectomy is early detection and prevention of colorectal cancer. This procedure also can be used to treat areas of bleeding or stricture. Use of bipolar and unipolar coagulators, use of heater probes, and injections of sclerosing agents or vasoconstrictors are all possible during this procedure. Laser-compatible scopes provide laser therapy for bleeding lesions or colonic neoplasms. Bowel decompression can also be completed during the procedure.

Colonoscopy is performed while the patient is lying on the left side with the legs drawn up toward the chest. The patient’s position may be changed during the test to facilitate advancement of the scope. The procedure usually takes about 1 hour. Discomfort may result from instillation of air to expand the colon or from insertion and moving of the scope. Biopsy forceps or a cytology brush may be passed through the scope to obtain specimens for histology and cytology examinations. Potential complications of colonoscopy include cardiac dysrhythmias and respiratory depression resulting from the medications administered, vasovagal reactions, and circulatory overload or hypotension resulting from overhydration or underhydration during bowel preparation. Therefore, it is important to monitor the patient’s cardiac and respiratory function continuously. Oxygen saturation is monitored with a
finger or ear oximeter. Supplemental oxygen should be used as necessary.

**NURSING INTERVENTIONS**

The success of the procedure depends on how well the colon is prepared. Adequate colon cleansing provides optimal visualization and decreases the time needed for the procedure. First, the patient should limit the intake of liquids for 24 to 72 hours before the examination. Then, cleansing of the colon can be accomplished in various ways. The physician may prescribe a laxative for two nights before the examination and a Fleet’s or saline enema until the return runs clear the morning of the test. More frequently, however, polyethylene glycol electrolyte lavage solutions (Golytely, Colyte, NuLytely) are used as intestinal lavages for effective cleansing of the bowel. The patient maintains a clear liquid diet starting at noon the day before the procedure. Then the patient ingests lavage solutions orally at intervals over 3 to 4 hours. If necessary, the nurse can give this solution through a feeding tube if the patient is unable to swallow. Patients with a colostomy can receive this same bowel preparation. With the use of lavage solutions, bowel cleansing is fast (rectal effluent is clear in about 4 hours) and is tolerated fairly well by most patients. Side effects of the electrolyte solutions include nausea, bloating, cramps or abdominal fullness, fluid and electrolyte imbalance, and hypothermia (patients are often told to drink the preparation as cold as possible to make it more palatable). The side effects are especially problematic for elderly patients, and sometimes they have difficulty ingesting the required volume of solution. The use of lavage solutions is contraindicated in patients with intestinal obstruction or inflammatory bowel disease.

Additional nursing actions include the following:

- Instructing the patient not to take routine medications when the lavage solution is ingested; the medications will not be digested and therefore will be ineffective
- Advising the diabetic patient to consult with his or her physician about medication adjustment to prevent hyperglycemia or hypoglycemia resulting from dietary modifications required in preparation for the test
- Instructing all patients, especially the elderly, to maintain adequate fluid, electrolyte, and caloric intake while undergoing bowel cleansing

Special precautions must be taken for some patients. Implantable defibrillators and pacemakers are at high risk for malfunction if electrosurgical procedures (ie, polypectomy) are performed in conjunction with colonoscopy. A cardiologist should be consulted before the test is performed, and the defibrillator should be turned off. These patients require careful cardiac monitoring during the procedure. Colonoscopy cannot be performed if there is a suspected or documented colon perforation, acute severe diverticulitis, or fulminant colitis. Therapeutic colonoscopy may be contraindicated in patients with coagulopathies and in those receiving anticoagulation therapy, because of the high risk for excessive bleeding during and after the procedure. Nonsteroidal anti-inflammatory agents (NSAIDs), aspirin, ticlopidine, and pentoxifylline must be discontinued before the test and for 2 weeks after the procedure. Patients taking coumadin or heparin must consult the physician for specific instructions. Those with prosthetic heart valves or a history of endocarditis require prophylactic antibiotics before the procedure.

Informed consent is obtained before the test. The patient receives nothing by mouth (NPO) after midnight before the test, but most medications can be taken with a small amount of water; the physician should be consulted about medication use. Before the examination, the nurse may administer intravenously an opioid analgesic or a sedative (eg, midazolam) to provide moderate sedation and relieve anxiety during the procedure. Glucagon may be used, if needed, to relax the colonic musculature and to reduce spasm during the test. Elderly or debilitated patients may require a reduced dosage of these medications to decrease the risks of oversedation and cardiopulmonary complications.

During the procedure, the nurse monitors for changes in oxygen saturation, vital signs, color and temperature of the skin, level of consciousness, abdominal distention, vagal response, and pain intensity. After the procedure, patients who were sedated are maintained on bed rest until fully alert. Some will have abdominal cramps caused by increased peristalsis stimulated by the air insufflated into the bowel during the procedure. Immediately after the test, the nurse observes the patient for signs and symptoms of bowel perforation (eg, rectal bleeding, abdominal pain or distention, fever, focal peritoneal signs). If midazolam was used, the nurse explains its amnesic effects. It is important to provide written instructions, because the patient may be unable to recall verbal information. If the procedure is performed on an outpatient basis, someone must accompany and transport the patient home. After a therapeutic procedure, the nurse instructs the patient to report any bleeding to the physician.

**Small-Bowel Enteroscopy**

Technology for the use of the small-caliber transnasal endoscope to allow direct inspection of the wall of the small intestine continues to be developed. Two methods are being used at this time: the “push” and the “pull” endoscope methods. The “pull” endoscope is very long and flexible and has a balloon at its tip. When inflated, the balloon tip advances the scope by peristalsis through the small intestine. Reglan may be administered intravenously to assist passage. This procedure takes up to 10 hours to complete. The patient may be kept in the recovery area or sent home during this period. Once the scope has entered the distal ileum, the balloon is deflated and the tube is retracted slowly while the endoscopist examines the intestinal wall. “Push” endoscopes have been designed to be smaller in caliber and longer in length, while still allowing the use of biopsy forceps and probes (Lightdale, 2000). These two methods are especially useful in the evaluation of patients who have continued bleeding even after extensive diagnostic testing has identified no other problem area. They can also be used when biopsy of the small bowel is needed to diagnose malabsorption syndromes.

**Endoscopy Through Ostomy**

Endoscopy using a flexible endoscope through an ostomy stoma is useful for visualizing a segment of the small or large intestine. It may be indicated to evaluate an anastomosis, to screen for recurrent disease, or to visualize and treat bleeding in a segment of the bowel. Nursing interventions are similar to those for other endoscopic procedures.

**MANOMETRY AND ELECTROPHYSIOLOGIC STUDIES**

Manometry and electrophysiologic studies are methods for evaluating patients with GI motility disorders. The manometry test measures changes in intraluminal pressures and the coordination
of muscle activity in the GI tract. The pressures can be recorded manually, on a physiograph, or on a computer.

Esophageal manometry is used to detect motility disorders of the esophagus and the lower esophageal sphincter. Patients must refrain from eating or drinking for 8 to 12 hours before the test. Medications that could have a direct affect on motility (eg, calcium channel blockers, anticholinergic agents, sedatives) are withheld for 24 to 48 hours. A pressure-sensitive catheter is inserted through the nose and is connected to a transducer and a video recorder. The patient then swallows small amounts of water while the resultant pressure changes are recorded.

Gastroesophageal reflux disease is evaluated by performing esophageal manometry, which can be performed in conjunction with rectal sensory functioning tests. Phospho-Soda or a saline cleansing enema is administered 1 hour before the test. Positioning for the test is either the prone or the lateral position.

A rectal sensory function test is used to evaluate rectal sensory function and neuropathy. A catheter and balloon are passed into the rectum, and the balloon is inflated until the patient feels distention. Then the tone and pressure of the rectum and anal sphincter are measured. The results are especially helpful in the evaluation of patients with chronic constipation or fecal incontinence. It can be performed in conjunction with rectal sensory functioning tests. Enzyme analysis of the gastric juice may be useful in detecting motor or nerve dysfunction in the stomach.

**Defecography**

Defecography measures anorectal function. Very thick barium paste is instilled into the rectum, and then fluoroscopy is performed to assess the function of the rectum and anal sphincter while the patient attempts to expel the barium. The test requires no preparation. The use of scintigraphic techniques to measure rectal emptying of radioisotope-labeled artificial stool can provide more quantitative information.

Electrophysiological (EMG) studies can supplement anorectal manometry to measure the integrity and function of the anal sphincters in an effort to treat functional bowel incontinence and constipation.

**GASTRIC ANALYSIS, GASTRIC ACID STIMULATION TEST, AND pH MONITORING**

Analysis of the gastric juice yields information about the secretory activity of the gastric mucosa and the presence or degree of gastric retention in patients thought to have pyloric or duodenal obstruction. It is also useful for diagnosing diseases such as Zollinger-Ellison syndrome.

The patient is kept NPO for 8 to 12 hours before the procedure. Any medications that affect gastric secretions are withheld for 24 to 48 hours before the test. Smoking is not allowed on the morning before the test, because it increases gastric secretions. A small nasogastric tube with a catheter tip marked at various points is inserted through the nose. When the tube is at a point slightly less than 50 cm (21 inches) distant, it should be within the stomach, lying along the greater curvature. Once in place, the tube is secured to the patient’s cheek and the patient is placed in a semi-reclining position. The entire stomach contents are aspirated by gentle suction into a syringe, and gastric samples are collected every 15 minutes for the next hour.

The gastric acid stimulation test usually is performed in conjunction with gastric analysis. Histamine or pentagastrin is administered subcutaneously to stimulate gastric secretions. It is important to inform the patient that this injection may produce a flushed feeling. The nurse monitors blood pressure and pulse frequently to detect hypotension. Gastric specimens are collected after the injection every 15 minutes for 1 hour and are labeled to indicate the time of specimen collection after histamine injection. The volume and pH of the specimen are measured. In certain instances, cytophologic study by the Papanicolaou technique may be used to determine the presence or absence of malignant cells. Enzyme analysis of the gastric juice may be indicated.

Important diagnostic information to be gained from gastric analysis includes the ability of the mucosa to secrete HCl. This ability is altered in various disease states, including:

- Pernicious anemia—patients with this disease secrete no acid under basal conditions or after stimulation
- Severe chronic atrophic gastritis or gastric cancer—patients with these diseases secrete little or no acid
- Peptic ulcer—patients with peptic ulcers secrete some acid
- Duodenal ulcers—patients with duodenal ulcers usually secrete an excess amount of acid

Esophageal reflux of gastric acid may be diagnosed by ambulatory pH monitoring. The patient is NPO for 6 hours before the test, and all medications affecting gastric secretions are withheld for 24 to 36 hours before the test. A probe that measures pH is placed through the nose and into position about 5 inches above the lower esophageal sphincter. It is connected to an external recording device and is worn for 24 hours while the patient continues his or her normal daily activities. The end result is a computer analysis and graphic display of the results. This test allows for the direct correlation between chest pain and reflux episodes (Wolfe, 2000).

A Bernstein test may be performed to evaluate complaints of acid-related chest or epigastric pain. HCl is instilled through a small feeding tube positioned in the esophagus. This is done to try to elicit reported chest pain. Resultant signs and symptoms are compared with the usual symptoms the patient reports. However, since the advent of ambulatory pH monitoring, this previously popular evaluation tool is used infrequently (Wolfe, 2000).

**LAPAROSCOPY (PERITONEOSCOPY)**

Laparoscopy can be used for the diagnosis of GI disease. This procedure is performed through a small incision in the abdominal wall. Special fiberoptic laparoscopes allow direct visualization of the organs and structures within the abdomen, permitting visualization and identification of any growths, anomalies, and inflammatory processes. In addition, biopsy samples can be taken from the structures and organs as necessary. This procedure can
be used to evaluate peritoneal disease, chronic abdominal pain, abdominal masses, and gallbladder and liver disease. However, laparoscopy has not become an important diagnostic modality in patients with acute abdominal pain, because less invasive tools (ie, CT and MRI) are readily available (Wolfe, 2000). Laparoscopy usually requires general anesthesia and sometimes requires that the stomach and bowel be decompressed. Gas (usually carbon dioxide) is insufflated into the peritoneal cavity to create a working space for visualization. One of the most positive benefits of this procedure is that after visualization of a problem, excision (eg, removal of the gallbladder) can be performed at the same time, if appropriate.

### Pathophysiologic and Psychological Considerations

Abnormalities of the GI tract are numerous and represent every type of major pathology that can affect other organ systems, including bleeding, perforation, obstruction, inflammation, and cancer. Congenital, inflammatory, infectious, traumatic, and neoplastic lesions have been encountered in every portion, and at every site, along the length of the GI tract. As with all other organ systems, the GI tract is subject to circulatory disturbances, faulty nervous system control, and aging.

Apart from the many organic diseases to which the GI tract is susceptible, there are many extrinsic factors that can interfere with its normal function and produce symptoms. Stress and anxiety, for example, often find their chief expression in indigestion, anorexia, or motor disturbances of the intestines, sometimes producing constipation or diarrhea. In addition to the state of mental health, physical factors such as fatigue and an inadequate or abruptly changed dietary intake can markedly affect the GI tract.

When assessing and instructing the patient, the nurse should consider the variety of mental and physical factors that affect the function of the GI tract.

### Gerontologic Considerations

Normal physiologic changes of the GI system that occur with aging are identified in the accompanying Gerontologic Considerations box. The nurse should carefully assess and monitor signs and symptoms related to these changes. Age-related changes in the mouth include loss of teeth, diminished number of taste buds, decreased production of saliva, and atrophy of gingival tissue. These changes cause difficulty in chewing and swallowing. Changes in the esophagus include decreased muscle tone and weakness in the lower esophageal sphincter, leading to reflux and heartburn.

Decreased gastric motility leads to delayed gastric emptying. Atrophy of the mucosa causes a decrease in HCl production, and this can lead to food intolerances, malabsorption, or decrease in vitamin B12 absorption. Changes in the small and large intestine are evidenced largely by decreased motility and decreased transit time, which lead to complaints of indigestion and constipation. Other changes lead to decreased absorption of nutrients (dextrose, fats, calcium, and iron) in the large intestine. The nerve supply to the anal sphincter is sometimes impaired, causing fecal incontinence (Luekenotte, 2000).

---

### Critical Thinking Exercises

1. You are caring for a 24-year-old male patient who was admitted for acute abdominal pain. He has just arrived from the emergency room and is being scheduled for tests this afternoon. What laboratory tests would you expect to be ordered? He is scheduled for a CT and ultrasound in 2 hours. What preparation is needed for these tests? What preprocedure education is needed?

2. A 58-year-old patient assigned to you this morning has just left to go to the Endoscopy Suite, where she will undergo a colonoscopy. You know that your patient will receive moderate sedation during the procedure and that she will be returned to your care once she is fully alert. What should you anticipate in the course of recovery for your patient after the colonoscopy? What medications might be used for the moderate sedation, and what effects of those medications would you expect to see during the recovery period? Describe the potential complications that could occur and what you will monitor. What are the goals for care during this period?

Management of Patients With Oral and Esophageal Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Use the nursing process as a framework for care of patients with conditions of the oral cavity.
2. Describe the relationship of dental hygiene and dental problems to nutrition.
3. Describe the nursing management of patients with abnormalities of the lips, gums, teeth, mouth, and salivary glands.
4. Use the nursing process as a framework for care of patients with cancer of the oral cavity.
5. Identify the physical and psychosocial long-term needs of patients with oral cancer.
6. Use the nursing process as a framework for care of patients undergoing neck dissection.
7. Use the nursing process as a framework for care of patients with conditions of the esophagus.
8. Describe the various conditions of the esophagus and their clinical manifestations and management.
Because digestion normally begins in the mouth, adequate nutrition is related to good dental health and the general condition of the mouth. Any discomfort or adverse condition in the oral cavity can affect a person’s nutritional status. Changes in the oral cavity may influence the type and amount of food ingested as well as the degree to which food particles are properly mixed with salivary enzymes. Disease of the mouth or tongue can interfere with speech and thus affect communication and self-image. Esophageal problems related to swallowing can also adversely affect food and fluid intake, thereby jeopardizing general health and well-being. Given the close relationship between adequate nutritional intake and the structures of the upper gastrointestinal tract (lips, mouth, teeth, pharynx, esophagus), health teaching can help prevent disorders associated with these structures.

The oral cavity, which includes the lips, mouth, and gums, is subject to many disorders and diseases. Table 35-1 reviews common abnormalities, their possible causes, and nursing management. As identified in a report by the U.S. Surgeon General in 2000, oral health is a very important component of a person’s physical and psychological sense of well-being. Severe periodontal disease affects approximately 14% of adults 45 to 64 years of age and 23% of adults 65 to 74 years of age (US Department of Health and Human Services, 2000).

Disorders of the Teeth

DENTAL PLAQUE AND CARIES

Tooth decay is an erosive process that begins with the action of bacteria on fermentable carbohydrates in the mouth, which produces acids that dissolve tooth enamel. The extent of damage to the teeth depends on the following:

- The presence of dental plaque
- The strength of the acids and the ability of the saliva to neutralize them
- The length of time the acids are in contact with the teeth
- The susceptibility of the teeth to decay

Dental plaque is a gluey, gelatin-like substance that adheres to the teeth. The initial action that causes damage to a tooth occurs under dental plaque.

Dental decay begins with a small hole, usually in a fissure (a break in the tooth’s enamel) or in an area that is hard to clean. Left unchecked, the affected area penetrates the enamel into the dentin. Because dentin is not as hard as enamel, decay progresses more rapidly and in time reaches the pulp. When the blood, lymph vessels, and nerves are exposed, they become infected and an abscess may form, either within the tooth or at the tip of the root. Soreness and pain usually occur with an abscess. As the infection continues, the patient’s face may swell, and there may be pulsating pain. The dentist can determine by x-ray studies the extent of damage and the type of treatment needed. Treatment for dental caries includes fillings, dental implants, and extractions. If treatment is not successful, the tooth may need to be extracted. In general, dental decay is associated with young people, but older adults are subject to decay as well, particularly from drug-induced or age-related oral dryness (see the accompanying Gerontologic Considerations box).

Prevention

Measures used to prevent and control dental caries include practicing effective mouth care, reducing the intake of starches and sugars (refined carbohydrates), applying fluoride to the teeth or drinking fluoridated water, refraining from smoking, controlling diabetes, and using pit and fissure sealants (Chart 35-1).

MOUTH CARE

Healthy teeth must be conscientiously and effectively cleaned on a daily basis. Brushing and flossing are particularly effective in mechanically breaking up the bacterial plaque that collects around teeth.

Normal mastication (chewing) and the normal flow of saliva also aid greatly in keeping the teeth clean. Because many ill patients do not eat adequate amounts of food, they produce less saliva, which in turn reduces this natural tooth cleaning process. The nurse may need to assume the responsibility for brushing the patient’s teeth. In any case, merely wiping the patient’s mouth and teeth with a swab is ineffective. The most effective method is mechanical cleansing (brushing). If brushing is impossible, it is better to wipe the teeth with a gauze pad, then have the patient swish an antiseptic mouthwash several times before expectorating into an emesis basin. A soft-bristled toothbrush is more effective than a sponge or foam stick. The lips may be coated with a water-soluble gel to prevent drying.

DIET

Dental caries may be prevented by decreasing the amount of sugar and starch in the diet. Patients who snack should be encouraged to choose less cariogenic alternatives, such as fruits, vegetables, nuts, cheeses, or plain yogurt.

FLUORIDATION

Flouridation of public water supplies has been found to decrease dental caries. Some areas of the country have natural fluoridation; other communities have added fluoride to public water supplies. Flouridation may be achieved also by having a dentist apply a concentrated gel or solution to the teeth, adding fluoride to home

Glossary

achalasia: absent or ineffective peristalsis (wavelike contraction) of the distal esophagus accompanied by failure of the esophageal sphincter to relax in response to swallowing

dysphagia: difficulty swallowing

gastroesophageal reflux: back-flow of gastric or duodenal contents into the esophagus

hernia: protrusion of an organ or part of an organ through the wall of the cavity that normally contains it

lithotripsy: use of shock waves to break up or disintegrate stones

odynophagia: pain on swallowing

parotitis: inflammation of the parotid gland

pyrosis: heartburn

periapical abscess: abscessed tooth

sialadenitis: inflammation of the salivary glands

stomatitis: inflammation of the oral mucosa

temporomandibular disorders: a group of conditions that cause pain or dysfunction of the temporomandibular joint (TMJ) and surrounding structures

xerostomia: dry mouth

water supplies, using fluoridated toothpaste or mouth rinse, or using sodium fluoride tablets, drops, or lozenges.

**PIT AND FISSURE SEALANTS**
The occlusal surfaces of the teeth have pits and fissures, areas that are prone to caries. Some dentists apply a special coating to fill and seal these areas from potential exposure to cariogenic processes. These sealants last up to 7 years.

### DENTOALVEOLAR ABSCESS OR PERIAPICAL ABSCESS

Periapical abscess, more commonly referred to as an abscessed tooth, involves the collection of pus in the apical dental periosteum (fibrous membrane supporting the tooth structure) and

### Chart 35-1 • PATIENT EDUCATION

**Preventive Oral Hygiene**

- Brush teeth using a soft toothbrush at least two times daily. Hold toothbrush at a 45-degree angle between the brush and the gums and teeth. A small brush is better than a large brush. Gums and tongue surface should be brushed.
- Floss at least once daily.
- Use an antiplaque mouth rinse.
- Visit a dentist at least every 6 months, or when you have a chipped tooth, a lost filling, an oral sore that persists longer than 2 weeks, or a toothache.
- Avoid alcohol and tobacco products, including smokeless tobacco.
- Maintain adequate nutrition and avoid sweets.
- Replace toothbrush at first signs of wear, usually every 2 months.
the tissue surrounding the apex of the tooth (where it is sus-
pended in the jaw bone). The abscess has two forms: acute and
chronic. Acute periapical abscess is usually secondary to a suppu-
rative pulpitis (a pus-producing inflammation of the dental pulp)
that arises from an infection extending from dental caries. The
infection of the dental pulp extends through the apical foramen
of the tooth to form an abscess around the apex.

Chronic dentoalveolar abscess is a slowly progressive infectious
process. It differs from the acute form in that the process may
progress to a fully formed abscess without the patient’s knowing
it. The infection eventually leads to a “blind dental abscess,”
which is really a periapical granuloma. It may enlarge to as much
as 1 cm in diameter. It is often discovered on x-ray films and is
treated by extraction or root canal therapy, often with apicectomy
(removal of the apex of the tooth root).

Clinical Manifestations
The abscess produces a dull, gnawing, continuous pain, often
with a surrounding cellulitis and edema of the adjacent facial
structures, and mobility of the involved tooth. The gum opposite
the apex of the tooth is usually swollen on the cheek side. Swelling
and cellulitis of the facial structures may make it difficult for the
patient to open the mouth. In well-developed abscesses, there
may be a systemic reaction, fever, and malaise.

Management
In the early stages of an infection, a dentist or dental surgeon
may perform a needle aspiration or drill an opening into the pulp
chamber to relieve tension and pain and to provide drainage.
Usually, the infection will have progressed to a periapical abscess.
Drainage is provided by an incision through the gingiva down
to the jawbone. Pus (purulent material) escapes under pressure.
This procedure is commonly performed in the dentist’s office,
but it may be performed in an outpatient surgery center or a
same-day surgery department. After the inflammatory reaction
has subsided, the tooth may be extracted or root canal therapy
performed. Antibiotics may be prescribed.

Nursing Management
The nurse assesses the patient for bleeding after treatment and in-
structs the patient to use a warm saline or warm water mouth
rinse to keep the area clean. The patient is also instructed to take an-
tibiotics and analgesics as prescribed, to advance from a liquid diet
to a soft diet as tolerated, and to keep follow-up appointments.

MALOCCLUSION
Malocclusion is a misalignment of the teeth of the upper and lower
dental arcs when the jaws are closed. Malocclusion can be inher-
ited or acquired (from thumb-sucking, trauma, or some medical
conditions). Malocclusion makes the teeth difficult to clean and
can lead to decay, gum disease, and excess wear on supporting bone
and gum tissues. About 50% of the population has some form of
malocclusion. Correction of malocclusion requires an orthodontist
with special training, a patient who is motivated and cooperative,
and adequate time. Most treatments begin when the patient has
shed the last primary tooth and the last permanent successor has
erupted, usually at about 12 or 13 years of age, but treatment may
occur in adulthood. Preventive orthodontics may be started at age
5 years if malocclusion is diagnosed early. The need for teeth
straightening in adolescence is reduced if preventive orthodontics
is started with the primary teeth.

Management
People with malocclusion have an obviously misaligned bite or
crooked, crowded, widely spaced, or protruding teeth. To re-
align the teeth, the orthodontist gradually forces the teeth into
a new location by using wires or plastic bands (braces). These
devices may be unattractive, but this psychological burden must
be overcome if good results are to be achieved. In the final phase
of treatment, a retaining device is worn for several hours each
day to support the tissues as they adjust to the new alignment
of the teeth.

Nursing Management
The patient must practice meticulous oral hygiene, and the nurse
encourages the patient to persist in this important part of the
treatment. An adolescent undergoing orthodontic correction
who is admitted to the hospital for some other problem may have
to be reminded to continue wearing the retainer (if it does not
interfere with the problem requiring hospitalization).

Disorders of the Jaw
Abnormal conditions affecting the mandible (jaw) and of the
temporomandibular joint (which connects the mandible to the
temporal bone at the side of the head in front of the ear) include
congenital malformation, fracture, chronic dislocation, cancer,
and syndromes characterized by pain and limited motion. Tem-
poromandibular disorders and jaw surgery (a treatment common
in many structural abnormalities or cancer of the jaw) are presented
in this section.

TEMPOROMANDIBULAR DISORDERS
Temporomandibular disorders are categorized as follows (Na-
tional Oral Health Information Clearinghouse, 2000):
- Myofascial pain—a discomfort in the muscles controlling
  jaw function and in neck and shoulder muscles
- Internal derangement of the joint—a dislocated jaw, a dis-
  placed disc, or an injured condyle
- Degenerative joint disease—rheumatoid arthritis or osteo-
  arthritis in the jaw joint

Diagnosis and treatment of temporomandibular disorders re-
main somewhat ambiguous, but the condition is thought to affect
about 10 million people in the United States. Misalignment of the
joints in the jaw and other problems associated with the ligaments
and muscles of mastication are thought to result in tissue damage
and muscle tenderness. Suggested causes include arthritis of the
jaw, head injury, trauma or injury to the jaw or joint, stress, and
malocclusion (although research does not support malocclusion as
a cause).

Clinical Manifestations
Patients have pain ranging from a dull ache to throbbing, debili-
tating pain that can radiate to the ears, teeth, neck muscles, and fa-
cial sinuses. They often have restricted jaw motion and locking of
the jaw. They may hear clicking and grating noises, and chewing and swallowing may be difficult. Depression may occur in response to these symptoms.

**Assessment and Diagnostic Findings**

Diagnosis is based on the patient’s subjective symptoms of pain, limitations in range of motion, dysphagia, difficulty chewing, difficulty with speech, or hearing difficulties. Magnetic resonance imaging, x-ray studies, and an arthrogram may be performed.

**Management**

Although some practitioners think the role of stress in temporomandibular joint (TMJ) disorders is overrated, patient education in stress management may be helpful (to reduce grinding and clenching of teeth). Patients may also benefit from range-of-motion exercises. Pain management measures may include nonsteroidal anti-inflammatory drugs (NSAIDs), with the possible addition of opioids, muscle relaxants, or mild antidepressants. Occasionally, a bite plate or splint (plastic guard worn over the upper and lower teeth) may be worn to protect teeth from grinding; however, this is a short-term therapy. Conservative and reversible treatment is recommended. If irreversible surgical options are recommended, the patient is encouraged to seek a second opinion.

**SURGICAL MANAGEMENT**

Correction of mandibular structural abnormalities may require surgery involving repositioning or reconstruction of the jaw. Simple fractures of the mandible without displacement, resulting from a blow on the chin, and planned surgical interventions, as in the correction of long or short jaw syndrome, may require treatment by these means. Jaw reconstruction may be necessary in the aftermath of trauma from a severe injury or cancer, both of which can cause tissue and bone loss.

Mandibular fractures are usually closed fractures. Rigid plate fixation (insertion of metal plates and screws into the bone to approximate and stabilize the bone) is the current treatment of choice in many cases of mandibular fracture and in some mandibular reconstructive surgery procedures. Bone grafting may be performed to replace structural defects using bones from the patient’s own ilium, ribs, or cranial sites. Rib tissue may also be harvested from cadaver donors.

**Nursing Management**

The patient who has had rigid fixation should be instructed not to chew food in the first 1 to 4 weeks after surgery. A liquid diet is recommended, and dietary counseling should be obtained to ensure optimal caloric and protein intake.

**PROMOTING HOME AND COMMUNITY-BASED CARE**

The patient needs specific guidelines for mouth care and feeding. Any irritated areas in the mouth should be reported to the physician. The importance of keeping scheduled appointments for assessing the stability of the fixation appliance is emphasized.

Consultation with a dietitian may be indicated so that the patient and family can learn about foods that are high in essential nutrients and ways in which these foods can be prepared so that they can be consumed through a straw or spoon, while remaining palatable. Nutritional supplements may be recommended.

**Disorders of the Salivary Glands**

The salivary glands consist of the parotid glands, one on each side of the face below the ear; the submandibular and sublingual glands, both in the floor of the mouth; and the buccal gland, beneath the lips. About 1200 mL of saliva are produced daily. The glands’ primary functions are lubrication, protection against harmful bacteria, and digestion.

**PAROTITIS**

Parotitis (inflammation of the parotid gland) is the most common inflammatory condition of the salivary glands, although inflammation can occur in the other salivary glands as well. Mumps (epidemic parotitis), a communicable disease caused by viral infection and most commonly affecting children, is an inflammation of a salivary gland, usually the parotid.

Elderly, acutely ill, or debilitated people with decreased salivary flow from general dehydration or medications are at high risk for parotitis. The infecting organisms travel from the mouth through the salivary duct. The organism is usually *Staphylococcus aureus* (except in mumps). The onset of this complication is sudden, with an exacerbation of both the fever and the symptoms of the primary condition. The gland swells and becomes tense and tender. The patient feels pain in the ear, and swollen glands interfere with swallowing. The swelling increases rapidly, and the overlying skin soon becomes red and shiny.

Preventive measures are essential and include advising the patient to have necessary dental work performed before surgery. In addition, maintaining adequate nutritional and fluid intake, good oral hygiene, and discontinuing medications (eg, tranquilizers, diuretics) that can diminish salivation may help prevent the condition. If parotitis occurs, antibiotic therapy is necessary. Analgesics may also be prescribed to control pain. If antibiotic therapy is not effective, the gland may need to be drained by a surgical procedure known as parotidectomy. This procedure may be necessary to treat chronic parotitis.

**SIALADENITIS**

Sialadenitis (inflammation of the salivary glands) may be caused by dehydration, radiation therapy, stress, malnutrition, salivary gland calculi (stones), or improper oral hygiene. The inflammation is associated with infection by *S. aureus*, *Streptococcus viridans*, or pneumococcus. In hospitalized or institutionalized patients the infecting organism may be methicillin-resistant *S. aureus* (MRSA) (McQuone, 1999). Symptoms include pain, swelling, and purulent discharge. Antibiotics are used to treat infections. Massage, hydration, and corticosteroids frequently cure the problem. Chronic sialadenitis with uncontrolled pain is treated by surgical drainage of the gland or excision of the gland and its duct.

**SALIVARY CALCULUS (SIALOLITHIASIS)**

Sialolithiasis, or salivary calculi (stones), usually occurs in the submandibular gland. Salivary gland ultrasonography or sialography (x-ray studies filmed after the injection of a radiopaque substance into the duct) may be required to demonstrate obstruction of the duct by stenosis. Salivary calculi are formed mainly from calcium phosphate. If located within the gland, the calculi are irregular and vary in diameter from 3 to 30 mm. Calculi in the duct are small and oval.
Calculi within the salivary gland itself cause no symptoms unless infection arises; however, a calculus that obstructs the gland’s duct causes sudden, local, and often colicky pain, which is abruptly relieved by a gush of saliva. This characteristic symptom is often disclosed in the patient’s health history. On physical assessment, the gland is swollen and quite tender, the stone itself can be palpable, and its shadow may be seen on x-ray films.

The calculus can be extracted fairly easily from the duct in the mouth. Sometimes, enlargement of the ductal orifice permits the stone to pass spontaneously. Occasionally, lithotripsy, a procedure that uses shock waves to disintegrate the stone, may be used instead of surgical extraction for parotid stones and smaller sub-mandibular stones. Lithotripsy requires no anesthesia, sedation, or analgesia. Side effects can include local hemorrhage and swelling. Surgery may be necessary to remove the gland if symptoms and calculi recur repeatedly.

NEOPLASMS

Although they are uncommon, neoplasms (tumors or growths) of almost any type may develop in the salivary gland. Tumors occur more often in the parotid gland. The incidence of salivary gland tumors is similar in men and women. Risk factors include prior exposure to radiation to the head and neck. Diagnosis is based on the health history and physical examination and the results of fine needle aspiration biopsy.

Management of salivary gland tumors evokes controversy, but the common procedure involves partial excision of the gland, along with all of the tumor and a wide margin of surrounding tissue. Dissection is carefully performed to preserve the seventh cranial nerve (facial nerve), although it may not be possible to preserve the nerve if the tumor is extensive. If the tumor is malignant, radiation therapy may follow surgery. Radiation therapy alone may be a treatment choice for tumors that are thought to be contained or if there is risk of facial nerve damage from surgical intervention. Chemotherapy is usually used for palliative purposes. Local recurrences are common, and the recurrent growth usually is more aggressive than the original. It has also been observed that patients with salivary gland tumors have an increased incidence of second primary cancers (Bull, 2001).

Cancer of the Oral Cavity

Cancers of the oral cavity, which can occur in any part of the mouth or throat, are curable if discovered early. These cancers are associated with the use of alcohol and tobacco. The combination of alcohol and tobacco seems to have a synergistic carcinogenic effect. About 95% of cases of oral cancer occur in people older than 40 years of age, but the incidence is increasing in men younger than age 30 because of the use of smokeless tobacco, especially snuff (Centers for Disease Control and Prevention, 2002).

Cancer of the oral cavity accounts for less than 2% of all cancer deaths in the United States. Men are afflicted more often than women; however, the incidence of oral cancer in women is increasing, possibly because they use tobacco and alcohol more frequently than they did in the past. The 5-year survival rate for cancer of the oral cavity and pharynx is 55% for whites and 33% for African Americans. Of the 7400 annual deaths from oral cancer, the distribution by site is estimated as follows: tongue, 1700; mouth, 2000; pharynx, 2100; other, 1600 (American Cancer Society, Cancer Facts and Figures, 2002).

Chronic irritation by a warm pipestem or prolonged exposure to the sun and wind may predispose a person to lip cancer. Pre-disposing factors for other oral cancers are exposure to tobacco (including smokeless tobacco), ingestion of alcohol, dietary deficiency, and ingestion of smoked meats.

Pathophysiology

Malignancies of the oral cavity are usually squamous cell cancers. Any area of the oropharynx can be a site for malignant growths, but the lips, the lateral aspects of the tongue, and the floor of the mouth are most commonly affected.

Clinical Manifestations

Many oral cancers produce few or no symptoms in the early stages. Later, the most frequent symptom is a painless sore or mass that will not heal. A typical lesion in oral cancer is a painless indurated (hardened) ulcer with raised edges. Tissue from any ulcer of the oral cavity that does not heal in 2 weeks should be examined through biopsy. As the cancer progresses, the patient may complain of tenderness; difficulty in chewing, swallowing, or speaking; coughing of blood-tinged sputum; or enlarged cervical lymph nodes.

Assessment and Diagnostic Findings

Diagnostic evaluation consists of an oral examination as well as an assessment of the cervical lymph nodes to detect possible metastases. Biopsies are performed on suspicious lesions (those that have not healed in 2 weeks). High-risk areas include the buccal mucosa and gingiva for people who use snuff or smoke cigars or pipes. For those who smoke cigarettes and drink alcohol, high-risk areas include the floor of the mouth, the ventrolateral tongue, and the soft palate complex (soft palate, anterior and posterior tonsillar area, uvula, and the area behind the molar and tongue junction).

Medical Management

Management varies with the nature of the lesion, the preference of the physician, and patient choice. Surgical resection, radiation therapy, chemotherapy, or a combination of these therapies may be effective.

In cancer of the lip, small lesions are usually excised liberally; larger lesions involving more than one third of the lip may be more appropriately treated by radiation therapy because of superior cosmetic results. The choice depends on the extent of the lesion and what is necessary to cure the patient while preserving the best appearance. Tumors larger than 4 cm often recur.

Cancer of the tongue may be treated with radiation therapy and chemotherapy to preserve organ function and maintain quality of life. A combination of radioactive interstitial implants (surgical implantation of a radioactive source into the tissue adjacent to or at the tumor site) and external beam radiation may be used. If the cancer has spread to the lymph nodes, the surgeon may perform a neck dissection. Surgical treatments leave a less functional tongue; surgical procedures include hemiglossectomy (surgical removal of half of the tongue) and total glossectomy (removal of the tongue).

Often cancer of the oral cavity has metastasized through the extensive lymphatic channel in the neck region (Fig. 35-1), requiring a neck dissection and reconstructive surgery of the oral
Chapter 35
Management of Patients With Oral and Esophageal Disorders

965

A common reconstructive technique involves use of a radial forearm free flap (a thin layer of skin from the forearm along with the radial artery).

Nursing Management

The nurse assesses the patient’s nutritional status preoperatively, and a dietary consultation may be necessary. The patient may require enteral (through the intestine) or parenteral (intravenous) feedings before and after surgery to maintain adequate nutrition. If a radial graft is to be performed, an Allen test on the donor arm must be performed to ensure that the ulnar artery is patent and can provide blood flow to the hand after removal of the radial artery. The Allen test is performed by asking the patient to make a fist and then manually compressing the ulnar artery. The patient is then asked to open the hand into a relaxed, slightly flexed position. The palm will be pale. Pressure on the ulnar artery is released. If the ulnar artery is patent, the palm will flush within about 3 to 5 seconds.

Postoperatively, the nurse assesses for a patent airway. The patient may be unable to manage oral secretions, making suctioning necessary. If grafting was included in the surgery, suctioning must be performed with care to prevent damage to the graft. The graft is assessed postoperatively for viability. Although color should be assessed (white may indicate arterial occlusion, and blue mottling may indicate venous congestion), it can be difficult to assess the graft by looking into the mouth. A Doppler ultrasound device may be used to locate the radial pulse at the graft site and to assess graft perfusion.

Gerontologic Considerations
Denture Care

Many older adults wear dentures. Mouth care and regular checkups remain part of the denture-wearing older adult’s health promotion activities.

- Brush dentures twice a day.
- Remove dentures at night and soak them in water or a denture product. (Never put dentures in hot water, because they may warp.)
- Rinse mouth with warm salt water in the morning, after meals, and at bedtime.
- Clean well under partial dentures, where food particles tend to get caught.
- Consume nonsticky foods that have been cut into small pieces; chew slowly.
- See dentist regularly to assess and readjust fit.
normal findings. The patient is instructed to protrude the tongue and move it laterally. This provides the examiner with an opportunity to estimate the tongue’s size as well as its symmetry and strength (to assess the integrity of the 12th cranial nerve [hypoglossal]).

Further inspection of the ventral surface of the tongue and the floor of the mouth is accomplished by asking the patient to touch the roof of the mouth with the tip of the tongue. Any lesions of the mucosa or any abnormalities involving the frenulum or superficial veins on the undersurface of the tongue are assessed for location, size, color, and pain. This is a common area for oral cancer, which presents as a white or red plaque, an indurated ulcer, or a warty growth.

A tongue blade is used to depress the tongue for adequate visualization of the pharynx. It is pressed firmly beyond the midpoint of the tongue; proper placement avoids a gagging response. The patient is told to tip the head back, open the mouth wide, take a deep breath, and say “ah.” Often this flattens the posterior tongue and briefly allows a full view of the tonsils, uvula, and posterior pharynx (Fig. 35-2). These structures are inspected for color, symmetry, and evidence of exudate, ulceration, or enlargement. Normally, the uvula and soft palate rise symmetrically with a deep inspiration or “ah”; this indicates an intact vagus nerve (10th cranial nerve).

A complete assessment of the oral cavity is essential because many disorders, such as cancer, diabetes, and immunosuppressive conditions resulting from medication therapy or AIDS, may be manifested by changes in the oral cavity. The neck is examined for enlarged lymph nodes (adenopathy).

Nursing Diagnoses

Based on all the assessment data, major nursing diagnoses may include the following:

- Impaired oral mucous membrane related to a pathologic condition, infection, or chemical or mechanical trauma (eg, medications, ill-fitting dentures)
- Imbalanced nutrition, less than body requirements, related to inability to ingest adequate nutrients secondary to oral or dental conditions
- Disturbed body image related to a physical change in appearance resulting from a disease condition or its treatment
- Fear of pain and social isolation related to disease or change in physical appearance
- Pain related to oral lesion or treatment
- Impaired verbal communication related to treatment
- Risk for infection related to disease or treatment
- Deficient knowledge about disease process and treatment plan

Planning and Goals

The major goals for the patient may include improved condition of the oral mucous membrane, improved nutritional intake, attainment of a positive self-image, relief of pain, identification of alternative communication methods, prevention of infection, and understanding of the disease and its treatment.

Nursing Interventions

**PROMOTING MOUTH CARE**

The nurse instructs the patient in the importance and techniques of preventive mouth care. If a patient cannot tolerate brushing or flossing, an irrigating solution of 1 teaspoon of baking soda to 8 ounces of warm water, half-strength hydrogen peroxide, or normal saline solution is recommended. The nurse reinforces the need to perform oral care and provides such care to patients who are unable to provide it for themselves.

If a bacterial or fungal infection is present, the nurse administers the appropriate medications and instructs the patient in how to administer the medications at home. The nurse monitors the patient’s physical and psychological response to treatment.

**Xerostomia,** dryness of the mouth, is a frequent sequela of oral cancer, particularly when the salivary glands have been exposed to radiation or major surgery. It is also seen in patients who are receiving psychopharmacologic agents, patients with HIV infection, and patients who cannot close the mouth and as a result become mouth-breathers. To minimize this problem, the patient is advised to avoid dry, bulky, and irritating foods and fluids, as well as alcohol and tobacco. The patient is also encouraged to increase intake of fluids (when not contraindicated) and to use a humidifier during sleep. The use of synthetic saliva, a moisturizing antibacterial gel such as Oral Balance, or a saliva production stimulant such as Salagen may be helpful.

**Stomatitis,** or mucositis, which involves inflammation and breakdown of the oral mucosa, is often a side effect of chemotherapy or radiation therapy. Prophylactic mouth care is started when the patient begins receiving treatment; however, mucositis may become so severe that a break in treatment is necessary. If a patient receiving radiation therapy has poor dentition, extraction of the teeth before radiation treatment in the oral cavity is often initiated to prevent infection. Many radiation therapy centers recommend the use of fluoride treatments for patients receiving radiation to the head and neck.

**ENSURING ADEQUATE FOOD AND FLUID INTAKE**

The patient’s weight, age, and level of activity are recorded to determine whether nutritional intake is adequate. A daily calorie count may be necessary to determine the exact quantity of food and fluid ingested. The frequency and pattern of eating are recorded to determine whether any psychosocial or physiologic factors are
A speech therapist is also consulted postoperatively.

Todays who cannot write so that they may point to needed items. Pictures is obtained preoperatively and given after surgery to patients who can use them to communicate in writing before surgery. Pen and paper are provided postoperatively to patients who can write so that they may point to needed items. A speech therapist is also consulted postoperatively.

Verbal communication may be impaired by radical surgery for oral cancer. It is therefore vital to assess the patient’s ability to communicate in writing before surgery. Pen and paper are provided postoperatively to patients who can write so that they may point to needed items. A speech therapist is also consulted postoperatively.

PREVENTING INFECTION
Leukopenia (a decrease in white blood cells) may result from radiation, chemotherapy, AIDS, and some medications used to treat HIV infection. Leukopenia reduces defense mechanisms, increasing the risk for infections. Malnutrition, which is also common among these patients, may further decrease resistance to infection. If the patient has diabetes, the risk of infection is further increased.

Laboratory results should be evaluated frequently and the patient’s temperature checked every 4 to 8 hours for an elevation that may indicate infection. Visitors who might transmit microorganisms are prohibited because the patient’s immunologic system is depressed. Sensitive skin tissues are protected from trauma to maintain skin integrity and prevent infection. Aseptic technique is necessary when changing dressings. Desquamation (shedding of the epidermis) is a reaction to radiation therapy that causes dryness and itching and can lead to a break in skin integrity and subsequent infection.

As described earlier, adequate nutrition is helpful in preventing infection. Signs of wound infection (redness, swelling, drainage, tenderness) are reported to the physician. Antibiotics may be prescribed prophylactically.

PROMOTING HOME AND COMMUNITY-BASED CARE
Teaching Patients Self-Care

The patient who is recovering from treatment of an oral condition is instructed about mouth care, nutrition, prevention of infection, and signs and symptoms of complications (Chart 35-2). Methods of preparing nutritious foods that are seasoned according to the patient’s preference and at the preferred temperature are explained. For some patients, it may be more convenient to use commercial baby foods than to prepare liquid and soft diets. The patient who cannot take foods orally may receive enteral or parenteral nutrition; the administration of these feedings is explained and demonstrated. The nurse can reduce the patient’s fear of pain by providing information about pain control methods.

CONTINUING CARE

The need for ongoing care in the home depends on the patient’s condition. The patient, the family members or others responsible for home care, the nurse, and other health care professionals (eg, speech therapist, nutritionist, psychologist) work together to prepare an individual plan of care.

If suctioning of the mouth or tracheostomy tube is required, the necessary equipment is obtained and the patient and care providers
are taught how to use it. Considerations include the control of odors and humidification of the home to keep secretions moist. The patient and the care providers are taught how to assess for obstruction, hemorrhage, and infection and what actions to take if they occur. The home care nurse may provide physical care, monitor for changes in the patient’s physical status (eg, skin integrity, nutritional status, respiratory function), and assess the adequacy of pain control measures. The nurse also assesses the patient’s and family’s ability to manage incisions, drains, and feeding tubes and the use of recommended strategies for communication. The ability of the patient and family to accept physical, psychological, and role changes is assessed and addressed.

Follow-up visits to the physician are important to monitor the patient’s condition and to determine the need for modifications in treatment and general care. The nurse reinforces instructions in an effort to promote the patient’s self-care and comfort.

Because patients and their family members and health care providers tend to focus on the most obvious needs and issues, the nurse reminds the patient and family about the importance of continuing health promotion and screening practices. Those patients who have not been involved in these practices in the past are educated about their importance and are referred to appropriate health care providers.

Evaluation

**EXPECTED PATIENT OUTCOMES**

Expected patient outcomes may include:

1. Shows evidence of intact oral mucous membranes
   a. Is free of pain and discomfort in the oral cavity
   b. Has no visible alteration in membrane integrity
   c. Identifies and avoids foods that are irritating (eg, nuts, pretzels, spicy foods)
   d. Describes measures that are necessary for preventive mouth care
   e. Complies with medication regimen
   f. Limits or avoids use of alcohol and tobacco (including smokeless tobacco)
2. Attains and maintains desirable body weight
3. Has a positive self-image
   a. Verbalizes anxieties
   b. Is able to accept change in appearance and modify self-concept accordingly
4. Attains an acceptable level of comfort
   a. Verbalizes that pain is absent or under control
   b. Avoids foods and liquids that cause discomfort
   c. Adheres to medication regimen
5. Has decreased fears related to pain, isolation, and the inability to cope
   a. Accepts that pain will be managed if not eliminated
   b. Freely expresses fears and concerns
6. Is free of infection
   a. Exhibits normal laboratory values
   b. Is afebrile
   c. Performs oral hygiene after every meal and at bedtime
7. Acquires information about disease process and course of treatment

**Neck Dissection**

Malignancies of the head and neck include those of the oral cavity, oropharynx, hypopharynx, nasopharynx, nasal cavity, paranasal sinus, and larynx (Fig. 35-3). (Laryngeal cancer is presented in Chapter 22.) These cancers account for fewer than 5% of all cancers. Depending on the location and stage, treatment may consist of radiation therapy, chemotherapy, surgery, or a combination of these modalities. Deaths from malignancies of the head and neck are primarily attributable not to recurrence at the primary site but to local-regional metastasis to the cervical lymph nodes in the neck. This often occurs by way of the lymphatics before the primary lesion has been treated. This local-regional metastasis is not amenable to surgical resection and responds poorly to chemotherapy and radiation therapy.

A radical neck dissection involves removal of all cervical lymph nodes from the mandible to the clavicle and removal of the sternocleidomastoid muscle, internal jugular vein, and spinal accessory muscle on one side of the neck. The associated morbidities include shoulder drop and poor cosmesis (visible neck depression). Modified radical neck dissection, which preserves one or more of the nonlymphatic structures, is used more often. A selective neck dissection (in comparison to a radical dissection) preserves one or more of the lymph node groups, the internal jugular vein, the sternocleidomastoid muscle, and the spinal accessory nerve (Fig. 35-4).

Reconstructive techniques may be performed with a variety of grafts. A cutaneous flap (skin and subcutaneous tissue), such as the deltopectoral flap, may be used. A more frequently used graft for head and neck reconstruction is a myocutaneous flap (subcutaneous tissue, muscle and skin). The pectoralis major muscle is usually used. A microvascular free flap may be used for large defects. This involves the transfer of muscle, skin, or bone with an artery and vein to the area of reconstruction, using microinstrumentation. Areas used for a free flap include the scapula, the radial area of the forearm, or the fibula. The fibula, which provides a larger bone area, may be used if mandibular reconstruction is involved.
NURSING PROCESS: THE PATIENT UNDERGOING A NECK DISSECTION

Assessment

Preoperatively, the patient’s physical and psychological preparation for major surgery is assessed, along with his or her knowledge of the preoperative and postoperative procedures. Postoperatively, the patient is assessed for complications such as altered respiratory status, wound infection, and hemorrhage. As healing occurs, neck range of motion is assessed to determine whether there has been a decrease in range of motion due to nerve or muscle damage.

Diagnosis

NURSING DIAGNOSES

Based on all the assessment data, major nursing diagnoses may include the following:

- Deficient knowledge about preoperative and postoperative procedures
- Ineffective airway clearance related to obstruction by mucus, hemorrhage, or edema
- Acute pain related to surgical incision
- Risk for infection related to surgical intervention secondary to decreased nutritional status, or immunosuppression from chemotherapy or radiation therapy
- Impaired tissue integrity secondary to surgery and grafting
- Impaired nutrition, less than body requirements, related to disease process or treatment
- Situational low self-esteem related to diagnosis or prognosis
- Impaired verbal communication secondary to surgical resection
- Impaired physical mobility secondary to nerve injury

COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Potential postoperative complications that may develop include the following:

- Hemorrhage
- Chyle fistula
- Nerve injury

Planning and Goals

The major goals for the patient include participation in the treatment plan, maintenance of respiratory status, absence of infection, viability of the graft, maintenance of adequate intake of food and fluids, effective coping strategies, attainment of comfort, effective communication, and absence of complications.

Nursing Interventions

PROVIDING PREOPERATIVE PATIENT EDUCATION

Before surgery, the patient should be informed about the nature and extent of the surgery, and what the postoperative period will be like. The patient is encouraged to ask questions and to express concerns about the upcoming surgery and the expected results. During this exchange, the nurse has an opportunity to assess the patient’s coping abilities, answer questions, and develop a plan for offering assistance. A sense of mutual understanding and rapport will make the postoperative experience less traumatic for the patient. The patient’s expressions of concern, anxieties, and fears can guide the nurse in providing support postoperatively.

PROVIDING GENERAL POSTOPERATIVE CARE

The general postoperative nursing interventions are similar to those presented in Chapter 20. For the patient who has had extensive neck surgery, specific postoperative interventions include maintenance of a patent airway and continuous assessment of respiratory status, wound care and oral hygiene, maintenance of adequate nutrition, and observation for hemorrhage or nerve injury.

MAINTAINING THE AIRWAY

After the endotracheal tube or airway has been removed and the effects of the anesthesia have worn off, the patient may be placed in Fowler’s position to facilitate breathing and promote comfort. This position also increases lymphatic and venous drainage, facilitates swallowing, and decreases venous pressure on the skin flaps.
In the immediate postoperative period, the nurse assesses for stridor (coarse, high-pitched sound on inspiration) by listening frequently over the trachea with a stethoscope. This finding must be reported immediately because it indicates obstruction of the airway. Signs of respiratory distress, such as dyspnea, cyanosis, changes in mental status, and changes in vital signs, are assessed because they may suggest edema, hemorrhage, inadequate oxygenation, or inadequate drainage.

Pneumonia may occur in the postoperative phase if pulmonary secretions are not removed. Coughing and deep breathing are encouraged to aid in the removal of secretions. The patient should assume a sitting position, with the nurse supporting the neck so that the patient can bring up excessive secretions. If this is ineffective, the patient’s respiratory tract may have to be suctioned. Care is taken to protect the suture lines during suctioning. If a tracheostomy tube is in place, suctioning is performed through the tube. The patient may also be instructed on use of Yankauer suction (tongue tip suction) to remove oral secretions. Temperature should not be taken orally.

**RELEIVING PAIN**

Pain and the patient’s fear of pain are assessed and managed. Patients with head and neck cancer often report less pain than patients with other types of cancer; however, the nurse needs to be aware that each person’s pain experience is individual. The nurse administers analgesics as prescribed and assesses their effectiveness.

**PROVIDING WOUND CARE**

Wound drainage tubes are usually inserted during surgery to prevent the collection of fluid subcutaneously. The drainage tubes are connected to portable suction device (eg, Jackson-Pratt), and the container is emptied periodically. Between 80 and 120 mL of serosanguineous drainage may drain over the first 24 hours. Excessive drainage may be indicative of a chyle fistula or hemorrhage (see later discussion). If dressings are present, they may need to be reinforced from time to time. Dressings are observed for evidence of hemorrhage and constriction, which impairs respiration and perfusion of the graft. The graft is assessed for color and temperature, and for the presence of a pulse if applicable, to determine viability. The graft should be pale pink and warm to the touch. The surgical incisions are also assessed for infection, which is reported immediately. Prophylactic antibiotics may be prescribed.

**MAINTAINING ADEQUATE NUTRITION**

Nutritional status is assessed preoperatively; early intervention to correct nutritional imbalances may decrease the risk of postoperative complications. Frequently, nutrition is less than optimal because of inadequate intake, and the patient often requires enteral or parenteral supplements preoperatively to attain a positive nitrogen balance. This therapy may need to be continued postoperatively if the patient cannot take enough nutrients by mouth. Supplements (eg, Ensure, Sustacal) that are nutritionally dense may help reestablish a positive nitrogen balance. They may be taken enterally by mouth, by nasogastric feeding tube, or by gastrostomy feeding tube. (See the Plan of Nursing Care for further discussion.)

The patient who is able to chew may take food by mouth; the level of the patient’s chewing ability will determine whether some diet modification (eg, soft, pureed, or liquid foods) is necessary. Food preferences should also be discussed with the patient. Oral care before eating may enhance the patient’s appetite, and oral care after eating is important to prevent infection and dental caries. Most patients are able to maintain and gain weight.

**SUPPORTING COPING MEASURES**

Preoperatively, information about the planned surgery is given to the patient and family. The psychological postoperative nursing intervention is aimed at supporting the patient who has had a change in body image or who has major concerns regarding the prognosis. The patient may have difficulty communicating and may be concerned about his or her ability to breathe and swallow normally. The nurse enlists the support of family or friends in encouraging and reassuring the patient that adjusting to the results of this surgery will take time.

The person who has had extensive neck surgery often is sensitive about his or her appearance. This can occur when the operative area is covered by bulky dressings, when the incision line is visible, or later after healing has occurred but the appearance of the neck and possibly the lower face has been significantly altered. If the nurse accepts the patient’s appearance and expresses a positive, optimistic attitude, the patient is more likely to be encouraged. The patient also needs an opportunity to express concerns regarding the success of the surgery and the prognosis. The American Cancer Society may be a resource to provide a volunteer to meet with the patient either preoperatively or postoperatively.

People with cancer of the head and neck frequently have used alcohol or tobacco before surgery; postoperatively, the patient is encouraged to abstain from these substances. Alternative methods of coping need to be explored. A referral to Alcoholics Anonymous may be appropriate.

**PROMOTING EFFECTIVE COMMUNICATION**

If a laryngectomy was performed, the nurse explores other methods of communicating with the patient and obtains a consultation with a speech/language therapist. Alternatives to verbal communication may include use of a pencil and paper or pointing to needed items on a picture pad. Alternative speech techniques, such as an electrolarynx (a mechanical device held against the neck) or esophageal speech, may be taught by a speech/language therapist.

**MAINTAINING PHYSICAL MOBILITY**

Excision of muscles and nerves results in weakness at the shoulder that can cause shoulder drop, a forward curvature of the shoulder. Many problems can be avoided with a conscientious exercise program. These exercises are usually begun after the drains have been removed and the neck incision is sufficiently healed. The purpose of the exercises depicted in Figure 35-5 is to promote maximal shoulder function and neck motion after surgery. Physical therapists and occupational therapists can assist patients in performing these exercises.

**MONITORING AND MANAGING POTENTIAL COMPLICATIONS**

**Hemorrhage**

Hemorrhage may occur from carotid artery rupture as a result of necrosis of the graft or damage to the artery itself from tumor or infection. The following measures are indicated:

- Vital signs are assessed. Tachycardia, tachypnea, and hypotension may indicate hemorrhage and impending hypovolemic shock.
- The patient is instructed to avoid the Valsalva maneuver to prevent stress on the graft and carotid artery.
- Signs of impending rupture, such as high epigastric pain or discomfort, are reported.
• Dressings and wound drainage are observed for excessive bleeding.
• If hemorrhage occurs, assistance is summoned immediately.
• Hemorrhage requires the continuous application of pressure to the bleeding site or major associated vessel.
• Although some advocate placing the patient in modified Trendelenburg position to maintain blood pressure, others recommend that the head of the patient’s bed be elevated to maintain airway patency and prevent aspiration.
• A controlled, calm manner will allay the patient’s anxiety.
• The surgeon is notified immediately, because a vascular or ligature tear requires surgical intervention.

Chyle Fistula
A chyle fistula (milk-like drainage from the thoracic duct into the thoracic cavity) may develop as a result of damage to the thoracic duct during surgery. The diagnosis is made if there is excess drainage which has a 3% fat content and a specific gravity of 1.012 or greater. Treatment of a small leak (500 mL or less) includes application of a pressure dressing and a diet of medium-chain fatty acids or parenteral nutrition. Surgical intervention to repair the damaged duct is necessary for larger leaks.

Nerve Injury
Nerve injury can occur if the cervical plexus or spinal accessory nerves are severed during surgery. Because lower facial paralysis may occur as a result of injury to the facial nerve, this complication is observed for and reported. Likewise, if the superior laryngeal nerve is damaged, the patient may have difficulty swallowing liquids and food because of the partial lack of sensation of the glottis. Speech therapy may be indicated to assist with the problems related to nerve injury.

PROMOTING HOME AND COMMUNITY-BASED CARE

Teaching Patients Self-Care
The patient and care provider will require instructions about management of the wound, the dressing, and any drains that remain in place. Patients who require oral suctioning or who have a tracheostomy may be very anxious about their care at home; the transition to home can be eased if the care provider is given several opportunities to demonstrate the ability to meet the patient’s needs (Chart 35-3).

If the patient cannot take food by mouth, detailed instructions and demonstration of enteral or parenteral feedings will be required. Education in techniques of effective oral hygiene is also important.
Continuing Care
A referral for home care nursing may be necessary in the early period after discharge. The nurse will assess healing, ensure that feedings are being administered properly, and detect any complications. The home care nurse assesses the patient’s adjustment to changes in physical appearance and status, ability to communicate, and ability to eat normally. Physical and speech therapy also may be continued at home.

The patient is given information regarding local support groups such as “I Can Cope” or “New Voice Club,” if indicated. The local chapter of the American Cancer Society may be contacted for information and equipment needed for the patient.

Evaluation
EXPECTED PATIENT OUTCOMES
Expected patient outcomes may include:

1. Discusses expected course of treatment
2. Demonstrates good respiratory exchange
   a. Lungs are clear to auscultation
   b. Breathes easily with no shortness of breath
   c. Demonstrates ability to use suction effectively
3. Remains free of infection
   a. Maintains normal laboratory values
   b. Is afebrile
4. Graft is pink and warm to touch
5. Maintains adequate intake of foods and fluids
   a. Accepts altered route of feeding
   b. Is well hydrated
   c. Maintains or gains weight
6. Demonstrates ability to cope
   a. Discusses emotional responses to the diagnosis
   b. Attends support group meetings
7. Verbalizes comfort
8. Attains maximal mobility
   a. Adheres to physical therapy exercises
   b. Attains maximal range of motion

The Plan of Nursing Care presents an overview of the care of a patient undergoing a neck dissection.

Disorders of the Esophagus
The esophagus is a mucus-lined, muscular tube that carries food from the mouth to the stomach. It begins at the base of the pharynx and ends about 4 cm below the diaphragm. Its ability to transport food and fluid is facilitated by two sphincters. The upper esophageal sphincter, also called the hypopharyngeal sphincter, is located at the junction of the pharynx and the esophagus. The lower esophageal sphincter, also called the gastroesophageal sphincter, is located at the junction of the esophagus and the stomach. An incompetent lower esophageal sphincter allows reflux (backward flow) of gastric contents. There is no serosal layer of the esophagus; therefore, if surgery is necessary, it is more difficult to perform suturing or anastomosis.

DYSPHAGIA
Dysphagia (difficulty swallowing) is the most common symptom of esophageal disease. This symptom may vary from an uncomfortable feeling that a bolus of food is caught in the upper esophagus (before it eventually passes into the stomach) to acute pain on swallowing (odynophagia). Obstruction of food (solid and soft) and even liquids may occur anywhere along the esophagus. Often the patient can indicate that the problem is located in the upper, middle, or lower third of the esophagus.

There are many pathologic conditions of the esophagus, including motility disorders (achalasia, diffuse spasm), gastroesophageal reflux, hiatal hernias, diverticula, perforation, foreign bodies, chemical burns, benign tumors, and carcinoma.

ACHALASIA
Achalasia is absent or ineffective peristalsis of the distal esophagus, accompanied by failure of the esophageal sphincter to relax in response to swallowing. Narrowing of the esophagus just above the stomach results in a gradually increasing dilation of the esophagus in the upper chest. Achalasia may progress slowly and occurs most often in people 40 years of age or older.

Clinical Manifestations
The primary symptom of achalasia is difficulty in swallowing both liquids and solids. The patient has a sensation of food sticking in the lower portion of the esophagus. As the condition progresses, food is commonly regurgitated, either spontaneously or intentionally by the patient to relieve the discomfort produced by prolonged distention of the esophagus by food that will not pass into the stomach. The patient may also complain of chest pain and heartburn (pyrosis). Pain may or may not be associated with eating. There may be secondary pulmonary complications from aspiration of gastric contents.

Assessment and Diagnostic Findings
X-ray studies show esophageal dilation above the narrowing at the gastroesophageal junction. Barium swallow, computed tomography

### Plan of Nursing Care

**The Patient Who Has Undergone Neck Dissection**

<table>
<thead>
<tr>
<th>Nursing Interventions</th>
<th>Rationale</th>
<th>Expected Outcomes</th>
</tr>
</thead>
</table>
| **Nursing Diagnosis:** Ineffective airway clearance related to obstruction secondary to edema, hemorrhage, or inadequate wound drainage  
**Goal:** Maintenance of normal respiratory function |

1. Place the patient in Fowler’s position.  
   - Fowler’s position facilitates expansion of the lungs because the diaphragm is pulled downward and the abdominal viscera are pulled away from the lungs. Breathing is promoted. This position also increases lymphatic and venous drainage, decreases swallowing, and decreases venous pressure on the graft. Regurgitation and aspiration of stomach contents are prevented postoperatively.  
   - Achieves a normal respiratory rate  
   - Breathes comfortably  
   - Avoids use of accessory muscles of respiration  
   - Maintains vital signs within normal range  
   - Shows evidence of normal breath sounds  
   - Coughs effectively  
   - Maintains a patent airway  
   - Does not develop a mucus plug

2. Monitor vital signs according to postoperative routine.  
   - Edema, hemorrhage, or inadequate drainage will alter heart rate and respiratory distress. Tachypnea and restlessness may indicate respiratory distress.

3. Auscultate breath sounds as needed. In the immediate postoperative period, place the stethoscope over the trachea to assess for stridor.  
   - Abnormal breath sounds may indicate ineffective ventilation, decreased perfusion, and fluid accumulation. Stridor, a harsh, high-pitched sound primarily heard on inspiration, indicates airway obstruction.

4. Encourage deep breathing and coughing. Place the patient in a sitting position and support the neck area with both hands.  
   - Deep breathing before coughing promotes expansion of the airways and a more forceful cough. The coughing mechanism assists airway cilia with removal of secretions. Splinting the incision during coughing reduces strain and promotes the expulsion of secretions by allowing deeper inspirations.

5. Suction the airway as needed using sterile technique and a soft catheter.  
   - Suctioning assists in removal of secretions that the patient may be unable to cough up, thereby assisting with maintaining a patent airway.

6. Provide humidified air or oxygen if the patient has a tracheostomy.  
   - Keeps secretions thin.

**Nursing Diagnosis:** Risk for infection  
**Goal:** Absence of infection

1. Instruct the patient in preoperative and postoperative oral hygiene using slightly alkaline solutions such as 8 oz of water mixed with 1 teaspoon of baking soda, or normal saline solution, every 4 hours.  
   - Oral care decreases oral bacteria, thereby decreasing the risk of bacterial infection postoperatively. Hydrogen peroxide should not be used, because it may break down fresh granulation tissue.  
   - Patient performs oral hygiene preoperatively and postoperatively every 4 hours  
   - Mouth remains clean  
   - Wound drains less than 200 mL of serosanguineous drainage on the first postoperative day  
   - No hematoma at skin graft  
   - Serosanguineous drainage is within normal limits  
   - Dressing remains intact with no constriction of airway or blood flow  
   - Wound and surrounding skin remain clean and free of infection  
   - Patient is afebrile with normal respirations and a normal heart rate  
   - Patient is alert and aware of surroundings

   - Suction drainage negates the need for pressure dressings because the skin flaps are pulled down tightly. Drainage should be 80–120 mL of serosanguineous secretions for the first 24 hours; then the secretions should decrease daily. Continuous bloody drainage indicates small vessel oozing.

<tr>
<th>Nursing Interventions</th>
<th>Rationale</th>
<th>Expected Outcomes</th>
</tr>
</thead>
<tbody>
<tr>
<td>3. Note drainage quantity and odor.</td>
<td>3. Purulent, malodorous drainage indicates an infection. Drainage greater than 300 mL in the first 24 hours is considered abnormal.</td>
<td></td>
</tr>
<tr>
<td>4. Assess condition of dressing and reinforce pressure dressings as needed. Assess for any possible constrictions that would affect respirations or decrease blood flow to graft.</td>
<td>4. If portable wound suction is not used, pressure dressings may be applied to obliterate dead spaces and provide immobilization. These dressings are reinforced, not changed, as needed.</td>
<td></td>
</tr>
<tr>
<td>5. Use aseptic technique to cleanse skin around the drains; change the dressings as ordered by surgeon (usually the second through fifth postoperative days).</td>
<td>5. Aseptic technique prevents wound contamination. Sterile saline effectively cleans the skin around the drains.</td>
<td></td>
</tr>
<tr>
<td>6. Monitor vital signs. Assess for symptoms of infection: chills, diaphoresis, altered level of consciousness.</td>
<td>6. An elevated temperature, tachypnea, and tachycardia may indicate an infection.</td>
<td></td>
</tr>
</tbody>
</table>

### Nursing Diagnosis: Impaired skin integrity

**Goal:** Maintenance of intact skin and viability of graft

1. Assess condition of graft for viability.  
   1. Cyanotic, cool graft indicates possible necrosis. (Pale graft indicates arterial thrombosis; purple graft indicates venous congestion.)

2. Assess wound for signs and symptoms of infection.  
   2. Infected wound interferes with healing and threatens the viability of the graft.

- Graft is pale pink in color and warm to touch
- Tissue blanches to gentle touch
- Graft has pulse via Doppler ultrasound
- Patient does not have wound infection

### Nursing Diagnosis: Imbalanced nutrition, less than body requirements, related to anorexia and dysphagia

**Goal:** Attainment/maintenance of adequate nutrition

1. Assess nutritional status preoperatively, consult with dietitian.  
   1. Poor nutritional status preoperatively impairs wound healing and increases potential for infection.

   2. A nasogastric tube may be in place for several days to administer enteral feedings.

3. Provide oral hygiene before and after meals.  
   3. Oral hygiene enhances appetite.

4. Assist with oral intake:  
   a. Offer easily chewed foods; mash or blenderize if necessary.
   b. Suggest that the head be tilted to the unaffected side when swallowing.
   c. Inquire whether privacy is desired when eating.
   d. Provide altered eating utensils as needed.

   4. Soft-textured foods facilitate swallowing. Passage of food may be tolerated better when the head is tilted to the unaffected side. Self-feeding difficulties may cause embarrassment and interfere with intake quantity.

- Does not have weight loss greater than 10% of body weight. (If weight loss is greater than 10%, supplements are given to maintain/increase weight and obtain positive nitrogen balance.)
- Tolerates tube feedings
- No signs of aspiration
- No sign of fistula
- Expresses a desire for food
- Swallows food easily
- Is comfortable eating alone or with others

</tbody>
</table>

(CT) of the esophagus, and endoscopy may be used for diagnosis; however, the diagnosis is confirmed by manometry, a process in which the esophageal pressure is measured by a radiologist or gastroenterologist.

**Management**

The patient should be instructed to eat slowly and to drink fluids with meals. As a temporary measure, calcium channel blockers and nitrates have been used to decrease esophageal pressure and improve swallowing. Injection of botulinum toxin (Botox) to quadrants of the esophagus via endoscopy has been helpful because it inhibits the contraction of smooth muscle. Periodic injections are required to maintain remission. If these methods are unsuccessful, pneumatic (forceful) dilation or surgical separation of the muscle fibers may be recommended (Streeter, 1999; Annese et al., 2000).

Achalasia may be treated conservatively by pneumatic dilation (Fig. 35-6). Pneumatic dilation has a high success rate. Although perforation is a potential complication, its incidence is low. The procedure can be painful; therefore, moderate sedation in the form of an analgesic or tranquilizer, or both, is administered for the treatment. The patient is monitored for perforation. Complaints of abdominal tenderness and fever may be indications of perforation (see later discussion).

Achalasia may be treated surgically by esophagomyotomy (Fig. 35-7). The procedure usually is performed laparoscopically, either with a complete lower esophageal sphincter myotomy and an antireflux procedure (see later discussion of fundoplasty), or without an antireflux procedure. The esophageal muscle fibers are separated to relieve the lower esophageal stricture. Although patients with a history of achalasia have a slightly higher incidence of esophageal cancer, long-term follow-up with esophagoscopy for early detection has not proved beneficial.

**DIFFUSE SPASM**

Diffuse spasm is a motor disorder of the esophagus. The cause is unknown, but stressful situations can produce contractions of the
Esophagus. It is more common in women and usually manifests in middle age.

**Clinical Manifestations**

Diffuse spasm is characterized by difficulty or pain on swallowing (dysphagia, odynophagia) and by chest pain similar to that of coronary artery spasm.

**Assessment and Diagnostic Findings**

Esophageal manometry, which measures the motility of the esophagus and the pressure within the esophagus, indicates that simultaneous contractions of the esophagus occur irregularly. Diagnostic x-ray studies after ingestion of barium show separate areas of spasm.

**Management**

Conservative therapy includes administration of sedatives and long-acting nitrates to relieve pain. Calcium channel blockers have also been used to manage diffuse spasm. Small, frequent feedings and a soft diet are usually recommended to decrease the esophageal pressure and irritation that lead to spasm. Dilation performed by bougienage (use of progressively sized flexible dilators), pneumatic dilation, or esophagomyotomy may be necessary if the pain becomes intolerable.
HIATAL HERNIA

The esophagus enters the abdomen through an opening in the diaphragm and empties at its lower end into the upper part of the stomach. Normally, the opening in the diaphragm encircles the esophagus tightly, and the stomach lies completely within the abdomen. In a condition known as hiatus (or hiatal) hernia, the opening in the diaphragm through which the esophagus passes becomes enlarged, and part of the upper stomach tends to move up into the lower portion of the thorax. Hiatal hernia occurs more often in women than men. There are two types of hiatal hernias: sliding and paraesophageal. Sliding, or type I, hiatal hernia occurs when the upper stomach and the gastroesophageal junction (GEJ) are displaced upward and slide in and out of the thorax (Fig. 35-8A). About 90% of patients with esophageal hiatal hernia have a sliding hernia. A paraesophageal hernia occurs when all or part of the stomach pushes through the diaphragm beside the esophagus (see Fig. 35-8B). Paraesophageal hernias may be further classified as types II, III, or IV, depending on the extent of herniation, with type IV having the greatest herniation.

Clinical Manifestations

The patient with a sliding hernia may have heartburn, regurgitation, and dysphagia, but at least 50% of patients are asymptomatic. Sliding hiatal hernia is often implicated in reflux. The patient with a paraesophageal hernia usually feels a sense of fullness after eating or may be asymptomatic. Reflux usually does not occur, because the gastroesophageal sphincter is intact. The complications of hemorrhage, obstruction, and strangulation can occur with any type of hernia.

Assessment and Diagnostic Findings

Diagnosis is confirmed by x-ray studies, barium swallow, and fluoroscopy.

Management

Management for an axial hernia includes frequent, small feedings that can pass easily through the esophagus. The patient is advised not to recline for 1 hour after eating, to prevent reflux or movement of the hernia, and to elevate the head of the bed on 4- to 8-inch (10- to 20-cm) blocks to prevent the hernia from sliding upward. Surgery is indicated in about 15% of patients. Medical and surgical management of a paraesophageal hernia is similar to that for gastroesophageal reflux; however, paraesophageal hernias may require emergency surgery to correct torsion (twisting) of the stomach or other body organ that leads to restriction of blood flow to that area.

DIVERTICULUM

A diverticulum is an outpouching of mucosa and submucosa that protrudes through a weak portion of the musculature. Diverticula may occur in one of the three areas of the esophagus—the pharyngoesophageal or upper area of the esophagus, the midesophageal area, or the epiphrenic or lower area of the esophagus—or they may occur along the border of the esophagus intramurally.

The most common type of diverticulum, which is found three times more frequently in men than in women, is Zenker’s diverticulum (also known as pharyngoesophageal pulsion diverticulum or a pharyngeal pouch). It occurs posteriorly through the cricopharyngeal muscle in the midline of the neck. It is usually seen in people older than 60 years of age. Other types of diverticula include midesophageal, epiphrenic, and intramural diverticula.

Midesophageal diverticula are uncommon. Symptoms are less acute, and usually the condition does not require surgery. Epiphrenic diverticula are usually larger diverticula in the lower esophagus just above the diaphragm. They are thought to be related to the improper functioning of the lower esophageal sphincter or to motor disorders of the esophagus. Intramural diverticulosis is the occurrence of numerous small diverticula associated with a stricture in the upper esophagus.

Clinical Manifestations

Symptoms experienced by the patient with a pharyngoesophageal pulsion diverticulum include difficulty swallowing, fullness in the neck, belching, regurgitation of undigested food, and gurgling

![Figure 35-8](https://example.com/image) Sliding esophageal and paraesophageal hernias. (A) Sliding esophageal hernia. The upper stomach and cardioesophageal junction have moved upward and slide in and out of the thorax. (B) Paraesophageal hernia. All or part of the stomach pushes through the diaphragm next to the gastroesophageal junction.)
The diverticulum, or pouch, becomes filled with food or liquid. When the patient assumes a recumbent position, undigested food is regurgitated, and coughing may be caused by irritation of the trachea. Halitosis and a sour taste in the mouth are also common because of the decomposition of food retained in the diverticulum.

Symptoms produced by midesophageal diverticula are less acute. One third of patients with epiphrenic diverticula are asymptomatic, and the remaining two thirds complain of dysphagia and chest pain. Dysphagia is the most common complaint of patients with intramural diverticulosis.

**Assessment and Diagnostic Findings**

A barium swallow may be performed to determine the exact nature and location of a diverticulum. Manometric studies are often performed for patients with epiphrenic diverticula to rule out a motor disorder. Esophagoscopy usually is contraindicated because of the danger of perforation of the diverticulum, with resulting mediastinitis (inflammation of the organs and tissues that separate the lungs). Blind insertion of a nasogastric tube should be avoided.

**Management**

Because pharyngoesophageal pulsion diverticulum is progressive, the only means of cure is surgical removal of the diverticulum. During surgery, care is taken to avoid trauma to the common carotid artery and internal jugular veins. The sac is dissected free and amputated flush with the esophageal wall. In addition to a diverticulectomy, a myotomy of the cricopharyngeal muscle is often performed to relieve spasticity of the musculature, which otherwise seems to contribute to a continuation of the previous symptoms. Postoperatively, the patient may have a nasogastric tube inserted at the time of surgery. The surgical incision must be avoided.

Surgery is indicated for epiphrenic and midesophageal diverticula only if the symptoms are troublesome and becoming worse. Treatment consists of a diverticulectomy and long myotomy. Intramural diverticula usually regress after the esophageal stricture is dilated.

**PERFORATION**

The esophagus is not an uncommon site of injury. Perforation may result from stab or bullet wounds of the neck or chest, trauma from motor vehicle crash, caustic injury from a chemical burn (described later), or inadvertent puncture by a surgical instrument during examination or dilation.

**Clinical Manifestations**

The patient has persistent pain followed by dysphagia. Infection, fever, leukocytosis, and severe hypotension may be noted. In some instances, signs of pneumothorax are observed.

**Assessment and Diagnostic Findings**

Diagnostic x-ray studies and fluoroscopy are used to identify the site of the injury.

**Management**

Because of the high risk of infection, broad-spectrum antibiotic therapy is initiated. A nasogastric tube is inserted to provide suction and to reduce the amount of gastric juice that can reflux into the esophagus and mediastinum. Nothing is given by mouth; nutritional needs are met by parenteral nutrition. Parenteral nutrition is preferred to gastrostomy because the latter might cause reflux into the esophagus.

Surgery may be necessary to close the wound, and postoperative nutritional support then becomes a primary concern. Depending on the incision site and the nature of surgery, the postoperative nursing management is similar to that for patients who have had thoracic or abdominal surgery.

**FOREIGN BODIES**

Many swallowed foreign bodies pass through the gastrointestinal tract without the need for medical intervention. However, some swallowed foreign bodies (eg, dentures, fish bones, pins, small batteries, items containing mercury or lead) may injure the esophagus or obstruct its lumen and must be removed. Pain and dysphagia may be present, and dyspnea may occur as a result of pressure on the trachea. The foreign body may be identified by x-ray film. Perforation may have occurred (see earlier discussion).

Glucagon, because of its relaxing effect on the esophageal muscle, may be injected intramuscularly. An endoscope (with a covered hood or overtube) may be used to remove the impacting food or object from the esophagus. A mixture consisting of sodium bicarbonate and tartaric acid may be used to increase intraluminal pressure by the formation of a gas. Caution must be used with this treatment because there is risk of perforation.

**CHEMICAL BURNS**

Chemical burns of the esophagus may be caused by undissolved medications in the esophagus. This occurs more frequently in the elderly than it does among the general adult population. A chemical burn may also occur after swallowing of a battery, which may release caustic alkaline. Chemical burns of the esophagus occur most often when a patient, either intentionally or unintentionally, swallows a strong acid or base (eg, lye). This patient is emotionally distraught as well as in acute physical pain. An acute chemical burn of the esophagus may be accompanied by severe burns of the lips, mouth, and pharynx, with pain on swallowing. There may be difficulty in breathing due to either edema of the throat or a collection of mucus in the pharynx.

The patient, who may be profoundly toxic, febrile, and in shock, is treated immediately for shock, pain, and respiratory distress. Esophagoscopy and barium swallow are performed as soon as possible to determine the extent and severity of damage. The patient is given nothing by mouth, and intravenous fluids are administered. A nasogastric tube may be inserted by the physician. Vomiting and gastric lavage are avoided to prevent further exposure of the esophagus to the caustic agent. The use of corticosteroids to reduce inflammation and minimize subsequent scarring and stricture formation is of questionable value. The value of the prophylactic use of antibiotics for these patients has also been questioned; however, these treatments continue to be prescribed (Schaffer & Herbert, 2000).

After the acute phase has subsided, the patient may need nutritional support via enteral or parenteral feedings. The patient may require further treatment to prevent or manage strictures of the esophagus. Dilation by bougienage may be sufficient, but dilation treatment may need to be repeated periodically. (In bougienage,
cylindrical rubber tubes of different sizes, called bougies, are advanced into the esophagus via the oral cavity. Progressively larger bougies are used to dilate the esophagus. The procedure usually is performed in the endoscopy suite or clinic by the gastroenterologist.) For strictures that do not respond to dilation, surgical management is necessary. Reconstruction may be accomplished by esophagectomy and colon interposition to replace the portion of esophagus removed.

GASTROESOPHAGEAL REFLUX DISEASE

Some degree of gastroesophageal reflux (back-flow of gastric or duodenal contents into the esophagus) is normal in both adults and children. Excessive reflux may occur because of an incompetent lower esophageal sphincter, pyloric stenosis, or a motility disorder. The incidence of reflux seems to increase with aging.

Clinical Manifestations

Symptoms of gastroesophageal reflux disease (GERD) may include pyrosis (burning sensation in the esophagus), dyspepsia (indigestion), regurgitation, dysphagia or odynophagia (difficulty swallowing, pain on swallowing), hypersalivation, and esophagitis. The symptoms may mimic those of a heart attack. The patient’s history aids in obtaining an accurate diagnosis.

Assessment and Diagnostic Findings

Diagnostic testing may include an endoscopy or barium swallow to evaluate damage to the esophageal mucosa. Ambulatory 12- to 36-hour esophageal pH monitoring is used to evaluate the degree of acid reflux. Bilirubin monitoring (Bilitec) is used to measure bile reflux patterns. Exposure to bile can cause mucosal damage (Aronson, 2000; Stein et al., 1999).

Management

Management begins with teaching the patient to avoid situations that decrease lower esophageal sphincter pressure or cause esophageal irritation. The patient is instructed to eat a low-fat diet; to avoid caffeine, tobacco, beer, milk, foods containing peppermint or spearmint, and carbonated beverages; to avoid eating or drinking 2 hours before bedtime; to maintain normal body weight; to avoid tight-fitting clothes; to elevate the head of the bed on 6- to 8-inch (15- to 20-cm) blocks; and to elevate the upper body on pillows. If reflux persists, the patient may be given medications such as antacids or histamine receptor blockers. Proton pump inhibitors (medications that decrease the release of gastric acid, such as lansoprazole [Prevacid] or rabeprazole [Aciphex]) may be used; however, there is concern that these products may increase intragastric bacterial growth and the risk for infection. In addition, the patient may receive prokinetic agents, which accelerate gastric emptying. These agents include bethanechol (Urecholine), domperidone (Motilium), and metoclopramide (Reglan). Metoclopramide has central nervous system complications with long-term use. The use of pectin-based products is now being studied (Aronson, 2000).

If medical management is unsuccessful, surgical intervention may be necessary. Surgical management involves a fundoplication (wrapping of a portion of the gastric fundus around the sphincter area of the esophagus). Fundoplication may be performed by laparoscopy.

BARRETT’S ESOPHAGUS

It is believed that long-standing untreated GERD may result in a condition known as Barrett’s esophagus. This has been identified as a precancerous condition that, if left untreated, can result in adenocarcinoma of the esophagus, which has a poor prognosis. It is more common among middle-aged white men; however, the incidence is increasing among women and among African Americans.

Clinical Manifestations

The patient complains of symptoms of GERD, notably frequent heartburn. The heartburn is a result of reflux, which eventually causes changes in the cells lining the lower esophagus. The patient may also complain of symptoms related to peptic ulcers or esophageal stricture, or both.

Assessment and Diagnostic Findings

An esophagogastroduodenoscopy (EGD) is performed. This usually reveals an esophageal lining that is red rather than pink. Biopsies are taken, and the cells resemble those of the intestine.

Management

Monitoring varies depending on the amount of cell changes. Some physicians may recommend a repeat EGD in 6 to 12 months if there are minor cell changes. Medical and surgical management is similar to that for GERD. Because this is a condition that is increasing in incidence, research is underway to determine the best monitoring and surgical interventions (Mueller et al., 2000; Stein et al., 1999).

BENIGN TUMORS OF THE ESOPHAGUS

Benign tumors can arise anywhere along the esophagus. The most common lesion is a leiomyoma (tumor of the smooth muscle), which can occlude the lumen of the esophagus. Most benign tumors are asymptomatic and are distinguished from cancerous lesions by a biopsy. Small lesions are excised during esophagoscopy; lesions that occur within the wall of the esophagus may require treatment via a thoracotomy.

CANCER OF THE ESOPHAGUS

In the United States, carcinoma of the esophagus occurs more than three times as often in men as in women. It is seen more frequently in African Americans than in Caucasians and usually occurs in the fifth decade of life. Cancer of the esophagus has a much higher incidence in other parts of the world, including China and northern Iran (Greenlee, 2001; Castell & Richter, 1999).

Chronic irritation is a risk factor for esophageal cancer. In the United States, cancer of the esophagus has been associated with ingestion of alcohol and with the use of tobacco. There seems to be an association between GERD and adenocarcinoma of the esophagus. People with Barrett’s esophagus (which is caused by chronic irritation of mucous membranes due to reflux of gastric and duodenal contents) have a higher incidence of esophageal cancer (Stein, 1999).

Pathophysiology

Esophageal cancer is usually of the squamous cell epidermoid type; however, the incidence of adenocarcinoma of the esophagus is increasing in the United States. Tumor cells may spread beneath the esophageal mucosa or directly into, through, and beyond the muscle layers into the lymphatics. In the latter stages,
obstruction of the esophagus is noted, with possible perforation into the mediastinum and erosion into the great vessels.

**Clinical Manifestations**

Many patients have an advanced ulcerated lesion of the esophagus before symptoms are manifested. Symptoms include dysphagia, initially with solid foods and eventually with liquids; a sensation of a mass in the throat; painful swallowing; substernal pain or fullness; and, later, regurgitation of undigested food with foul breath and hiccups. The patient first becomes aware of intermittent and increasing difficulty in swallowing. As the tumor progresses and the obstruction becomes more complete, even liquids cannot pass into the stomach. Regurgitation of food and saliva occurs, hemorrhage may take place, and progressive loss of weight and strength occurs from starvation. Later symptoms include substernal pain, persistent hiccup, respiratory difficulty, and foul breath. The delay between the onset of early symptoms and the time when the patient seeks medical advice is often 12 to 18 months. Anyone with swallowing difficulties should be encouraged to consult a physician immediately.

**Assessment and Diagnostic Findings**

Although new endoscopic techniques are being studied for screening and diagnosis of esophageal cancer, currently diagnosis is confirmed most often by EGD with biopsy and brushings. Bronchoscopy is performed, especially in tumors of the middle and the upper third of the esophagus, to determine whether the trachea has been affected and to help determine whether the lesion can be removed. Endoscopic ultrasound or mediastinoscopy is used to determine whether the cancer has spread to the nodes and other mediastinal structures. Cancer of the lower end of the esophagus may be caused by adenocarcinoma of the stomach that extends upward into the esophagus.

**Medical Management**

If esophageal cancer is found at an early stage, treatment goals may be directed toward cure; however, it is often found in late stages, making relief of symptoms the only reasonable goal of therapy. Treatment may include surgery, radiation, chemotherapy, or a combination of these modalities, depending on the extent of the disease.

Standard surgical management includes a total resection of the esophagus (esophagectomy) with removal of the tumor plus a wide tumor-free margin of the esophagus and the lymph nodes in the area. The surgical approach may be through the thorax or the abdomen, depending on the location of the tumor. When tumors occur in the cervical or upper thoracic area, esophageal continuity may be maintained by free jejunal graft transfer, in which the tumor is removed and the area is replaced with a portion of the jejunum (Fig. 35-9). A segment of the colon may be used, or the stomach can be elevated into the chest and the proximal section of the esophagus anastomosed to the stomach.

Tumors of the lower thoracic esophagus are more amenable to surgery than are tumors located higher in the esophagus, and gastrointestinal tract integrity is maintained by anastomosing the lower esophagus to the stomach.

Surgical resection of the esophagus has a relatively high mortality rate because of infection, pulmonary complications, or leakage through the anastomosis. Postoperatively, the patient will have a nasogastric tube in place that should not be manipulated. The patient is given nothing by mouth until x-ray studies confirm that the anastomosis is secure and not leaking.

**Nursing Management**

Intervention is directed toward improving the patient’s nutritional and physical condition in preparation for surgery, radiation therapy, or chemotherapy. A program to promote weight gain based on a high-calorie and high-protein diet, in liquid or soft form, is provided if adequate food can be taken by mouth. If this is not possible, parenteral or enteral nutrition is initiated. Nutritional status is monitored throughout treatment. The patient is informed about the nature of the postoperative equipment that will be used, including that required for closed chest drainage, nasogastric suction, parenteral fluid therapy, and gastric intubation. Immediate postoperative care is similar to that provided for patients undergoing thoracic surgery. After recovering from the effects of anesthesia, the patient is placed in a low Fowler’s position, and later in a Fowler’s position, to assist in preventing reflux of gastric secretions. The patient is observed carefully for regurgitation and dyspnea. A common postoperative complication is aspiration pneumonia. The patient’s temperature is monitored to detect any elevation that may indicate aspiration or seepage of fluid through the operative site into the mediastinum.

If jejunal grafting has been performed, the nurse checks for graft viability hourly for at least the first 12 hours. To make the graft visible, the surgeon usually brings a portion of the jejunum to the exterior neck by way of a small incision. Moist gauze covers the external portion of the graft. The gauze is removed briefly to assess the graft for color and to assess for the presence of a pulse by means of Doppler ultrasonography.
If an endoprosthesis has been placed or an anastomosis has been performed, a functioning continuum will exist between the throat and the stomach. Immediately after surgery, the nasogastric tube should be marked for position, and the physician is notified if displacement occurs. The nurse does not attempt to reinsert a displaced nasogastric tube, because damage to the anastomosis may occur. The nasogastric tube is removed 5 to 7 days after surgery, and a barium swallow is performed to assess for any anastomotic leak before the patient is allowed to eat.

Once feeding begins, the nurse encourages the patient to swallow small sips of water and, later, small amounts of pureed food. When the patient is able to increase food intake to an adequate amount, parenteral fluids are discontinued. If an endoprosthesis is used, it may easily become obstructed if food is not chewed sufficiently. After each meal, the patient remains upright for at least 2 hours to allow the food to move through the gastrointestinal tract. It is a challenge to encourage the patient to eat, because appetite is usually poor. Family involvement and home-cooked favorite foods may help the patient to eat. Antacids may help those with gastric distress.

If radiation is part of the therapy, the patient’s appetite is further depressed and esophagitis may occur, causing pain when food is eaten. Liquid supplements may be more easily tolerated.

Often, in either the preoperative or the postoperative period, an obstructed or nearly obstructed esophagus causes difficulty with excess saliva, so that drooling becomes a problem. Oral suction may be used if the patient is unable to handle oral secretions, or a wick-type gauze may be placed at the corner of the mouth to direct secretions to a dressing or emesis basin. The possibility that the patient may aspirate saliva into the tracheobronchial tree and develop pneumonia is of great concern.

When the patient is ready to go home, the family is instructed about how to promote nutrition, what observations to make, what measures to take if complications occur, how to keep the patient comfortable, and how to obtain needed physical and emotional support.

**NURSING PROCESS: THE PATIENT WITH A CONDITION OF THE ESOPHAGUS**

**Assessment**

Emergency conditions of the esophagus (perforation, chemical burns) usually occur in the home or away from medical help and require emergency medical care. The patient is treated for shock and respiratory distress and transported as quickly as possible to a medical facility. Foreign bodies in the esophagus do not pose an immediate threat to life unless pressure is exerted on the trachea, resulting in dyspnea or interfering with respiration, or unless there is leakage of caustic alkali from a battery. Educating the public to prevent inadvertent swallowing of foreign bodies or corrosive agents is a major health issue.

For nonemergency symptoms, a complete health history may reveal the nature of the esophageal disorder. The nurse asks about the patient’s appetite. Has it remained the same, increased, or decreased? Is there any discomfort with swallowing? If so, does it occur only with certain foods? Is it associated with pain? Does a change in position affect the discomfort? The patient is asked to describe the pain. Does anything aggravate it? Are there any other symptoms that occur regularly, such as regurgitation, nocturnal regurgitation, eructation (belching), heartburn, substernal pressure, a sensation that food is sticking in the throat, a feeling of becoming full after eating a small amount of food, nausea, vomiting, or weight loss? Are the symptoms aggravated by emotional upset? If the patient reports any of these symptoms, the nurse asks about the time of their occurrence, their relationship to eating, and factors that relieve or aggravate them (eg, position change, belching, antacids, vomiting).

This history also includes questions about past or present causative factors, such as infections and chemical, mechanical, or physical irritants; the degree to which alcohol and tobacco are used; and the amount of daily food intake. The nurse determines whether the patient appears emaciated and auscultates the patient’s chest to determine whether pulmonary complications exist.

**Nursing Diagnosis**

Based on the assessment data, the nursing diagnoses may include the following:

- **Imbalanced nutrition, less than body requirements, related to difficulty swallowing**
- **Risk for aspiration related to difficulty swallowing or to tube feeding**
- **Acute pain related to difficulty swallowing, ingestion of an abrasive agent, tumor, or frequent episodes of gastric reflux**
- **Deficient knowledge about the esophageal disorder, diagnostic studies, medical management, surgical intervention, and rehabilitation**

**Planning and Goals**

The major goals for the patient may include attainment of adequate nutritional intake, avoidance of respiratory compromise from aspiration, relief of pain, and increased knowledge level.

**Nursing Interventions**

**ENCOURAGING ADEQUATE NUTRITIONAL INTAKE**

The patient is encouraged to eat slowly and to chew all food thoroughly so that it can pass easily into the stomach. Small, frequent feedings of nonirritating foods are recommended to promote digestion and to prevent tissue irritation. Sometimes liquid swallowed with food helps the food pass through the esophagus. Food should be prepared in an appealing manner to help stimulate the appetite. Irritants such as tobacco and alcohol should be avoided.

A baseline weight is obtained, and daily weights are recorded. The patient’s intake of nutrients is assessed.

**DECREASING RISK OF ASPIRATION**

The patient who has difficulty swallowing or difficulty handling secretions should be kept in at least a semi-Fowler’s position to decrease the risk of aspiration. The patient can be instructed in the use of oral suction to decrease the risk of aspiration further.

**RELIEVING PAIN**

Small, frequent feedings are recommended, because large quantities of food overload the stomach and promote gastric reflux. The patient is advised to avoid any activities that increase pain, and to remain upright for 1 to 4 hours after each meal to prevent reflux. The head of the bed should be placed on 4- to 8-inch (10- to 20-cm) blocks. Eating before bedtime is discouraged.

The patient is advised that excessive use of over-the-counter antacids can cause rebound acidity. Antacid use should be directed by the primary care provider, who can recommend the daily, safe dose needed to neutralize gastric juices and prevent esophageal...
irritation. Histamine₂ antagonists are administered as prescribed to decrease gastric acid irritation.

**PROVIDING PATIENT EDUCATION**

The patient is prepared physically and psychologically for diagnostic tests, treatments, and possible surgical intervention. The principal nursing interventions include reassuring the patient and discussing the procedures and their purposes. Some disorders of the esophagus evolve over time, whereas others are the result of trauma (eg, chemical burns, perforation). In instances of trauma, the emotional and physical preparation for treatment is more difficult because of the short time available and the circumstances of the injury. Treatment interventions must be evaluated continually; the patient is given sufficient information to participate in care and diagnostic tests. If endoscopic diagnostic methods are used, the patient is instructed regarding the moderate sedation that will be used during the procedure. If procedures are being performed on an outpatient basis with the use of moderate sedation, the patient is instructed to have someone available to drive him or her home after the procedure. If surgery is required, immediate and long-term evaluation is similar to that for a patient undergoing thoracic surgery.

**PROMOTING HOME AND COMMUNITY-BASED CARE**

**Teaching Patients Self-Care**

The self-care required of the patient depends on the nature of the disorder and on the surgery or treatment measures used (eg, diet, positioning, medications). If an ongoing condition exists, the nurse helps the patient plan for needed physical and psychological adjustments and for follow-up care (Chart 35-4).

Special equipment, such as suction or enteral or parenteral feeding devices, may be required. The patient may need assistance in planning meals, using medications as prescribed, and resuming activities. Education about nutritional requirements and how to measure the adequacy of nutrition is important. Elderly and debilitated patients in particular often need assistance and education in ways to adjust to their limitations and to resume activities that are important to them.

**Continuing Care**

Patients with chronic esophageal conditions require an individualized approach to their management at home. Foods may need to be prepared in a special way (blended foods, soft foods), and the patient may need to eat more frequently (eg, four to six small servings per day). The medication schedule is adjusted to the patient’s daily activities as much as possible. Analgesic medications and antacids can usually be taken as needed every 3 to 4 hours.

Postoperative home health care focuses on nutritional support, management of pain, and respiratory function. Some patients are discharged from the hospital with enteral feeding by means of a gastrostomy or jejunostomy tube or parenteral nutrition. The patient and care provider need specific instructions regarding management of the equipment and treatments. Home care visits by a nurse may be necessary to assess the patient’s care and the care provider’s ability to provide the necessary care. (See Chapter 36 for more information about parenteral nutrition and management of the patient with a gastrostomy.) For some patients, a multidisciplinary team comprising a dietitian, a social worker, and family members is helpful. Hospice care is appropriate for some patients.

**Evaluation**

**EXPECTED PATIENT OUTCOMES**

Expected patient outcomes may include:

1. Achieves an adequate nutritional intake
   a. Eats small, frequent meals
   b. Drinks water with small servings of food
   c. Avoids irritants (alcohol, tobacco, very hot beverages)
   d. Maintains desired weight
2. Does not aspirate or develop pneumonia
   a. Maintains upright position during feeding
   b. Uses oral suction equipment effectively
3. Is free of pain or able to control pain within a tolerable level
   a. Avoids large meals and irritating foods
   b. Takes medications as prescribed and with adequate fluids (at least 4 ounces), and remains upright for at least 10 minutes after taking medications
   c. Maintains an upright position after meals for 1 to 4 hours
   d. Reports that there is less eructation and chest pain
4. Increases knowledge level of esophageal condition, treatment, and prognosis
   a. States cause of condition
   b. Discusses rationale for medical or surgical management and diet or medication regimen
   c. Describes treatment program
   d. Practices preventive measures so injuries are avoided

**Critical Thinking Exercises**

1. You are interviewing a patient in the medical clinic. The patient is complaining of difficulty swallowing as well as indigestion. Describe how you would continue to assess this patient to obtain the additional information that is
needed. Identify the various factors that may be causing this patient’s symptoms.

2. You are caring for two postoperative patients. One patient is being treated for cancer of the mouth, the other for cancer of the esophagus. How will the nutritional care of these two patients differ? Describe the communication needs and psychosocial needs of these patients.

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Describe the purposes and types of GI intubation.
2. Discuss nursing management of the patient who has a nasogastric or nasoenteric tube.
3. Use the nursing process as a framework for care of the patient receiving an enteral feeding.
4. Explain the preoperative and postoperative care of the patient with a gastrostomy.
5. Use the nursing process as a framework for care of the patient with a gastrostomy.
6. Identify the purposes and uses of parenteral nutrition.
7. Use the nursing process as a framework for care of the patient receiving parenteral nutrition.
8. Describe the nursing measures used to prevent complications from parenteral nutrition.
Chapter 36 Gastrointestinal Intubation and Special Nutritional Modalities

This chapter presents several topics related to gastrointestinal (GI) intubation. Nursing management topics relate to managing the care of patients with nasogastric (NG) and nasoenteric tubes and gastrostomies, providing tube feedings, and teaching points related to home health care and nutritional therapy. In addition, parenteral nutrition is presented, including general indications for this nutritional modality and nursing care of patients receiving these support measures.

Gastrointestinal Intubation

GI intubation is the insertion of a rubber or plastic tube into the stomach, the duodenum (first section of the small intestine), or the intestine. The tube may be inserted through the mouth, the nose, or the abdominal wall. The tubes can be short, medium, or long, depending on their intended use: nasogastric (NG) tubes are short, nasoduodenal tubes are of medium length, and nasoenteric tubes are long. GI intubation may be performed for the following reasons:

- To decompress the stomach and remove gas and fluid
- To lavage the stomach and remove ingested toxins
- To diagnose disorders of GI motility and other disorders
- To administer medications and feedings
- To treat an obstruction
- To compress a bleeding site
- To aspirate gastric contents for analysis

A variety of tubes are used for decompression, aspiration, and lavage. The Sengstaken-Blakemore tube is a type of NG tube used to treat bleeding esophageal varices (see Chapter 39). Orogastric tubes are large-bore tubes with wide proximal outlets for removal of particles of ingested substances (eg, pills); they are primarily used in emergency departments. Various other tubes are used to administer feedings and medications. The tubes are made of various materials (rubber, polyurethane, silicone), and they vary in length (90 cm to 3 m [3 to 10 ft]), in size (6 to 18 French [Fr]), in purpose, and in placement in the GI tract (stomach, duodenum, jejunum) (Table 36-1). Any solution administered through a tube is either poured through a syringe or delivered by a drip mechanism regulated by gravity or by an electric pump. Aspiration (suctioning) to remove gas and fluids is accomplished with the use of a syringe, an electric suction machine, or a wall suction outlet.

SHORT TUBES

An NG tube or short tube is introduced through the nose into the stomach, often before or during esophageal or stomach surgery. Commonly used short tubes include the Levin tube and the gastric sump tube. Short tubes are used in adults primarily to remove fluid and gas from the upper GI tract or to obtain a specimen of gastric contents for laboratory studies. They are occasionally used for the short-term (3 to 4 weeks) administration of medications or feedings.

Levin Tube

The Levin tube has a single lumen (the hollow part of the tube), ranges from 14 to 18 Fr in size, and is made of plastic or rubber with openings near its tip. It is 125 cm (50 in) long. Circular markings at specific points on the tube serve as guides for insertion. A marking is made on the tube to indicate the midpoint. The tube is advanced cautiously until this marking reaches the patient’s nostril, suggesting that the tube is in the stomach. Placement is checked by observing the characteristics of the aspirate and by testing the pH (which varies according to the source of the aspirate). Seeing the tube on an x-ray study is the only sure way to verify its location. The Levin tube is connected to low intermittent suction (30 to 40 mm Hg). Intermittent suction is used to avoid erosion or tearing of the stomach lining, which can result from constant adherence of the tube’s lumen to the mucosal lining of the stomach.

Glossary

antireflux valve: valve that prevents return or backward flow of fluid
aspiration: breathing of fluids or foods into the trachea and lungs; removal of substance by suction
bolus: a feeding administered into the stomach in large amounts and at designated intervals
central venous access device (CVAD): a device designed and used for long-term administration of medications and fluids into central veins
cyclic feeding: periodic feeding/infusion given over a short period (8 to 12 hours)
decompression (intestinal): removal of intestinal contents to prevent gas and fluid from distending the coils of the intestine
dumping syndrome: rapid emptying of the stomach contents into the small intestine; characterized by sweating and weakness
duodenum: the first part of the small intestine, which connects with the pylorus of the stomach and extends to the jejunum
feeding tube: tube through which nutritional products, water, and other fluids can be introduced into the GI tract
gastrostomy: surgical creation of an opening into the stomach for the purpose of administering foods and fluids
irrigation: flushing of the tube with water or other fluids to clear it
jejunum: second portion of the small intestine, extending from the duodenum to the ileum
low-profile gastrostomy device (LPGD, G-button): an enteral feeding access device that is flush with the skin and is used for long-term feeding
nasoduodenal tube: tube inserted through the nose into the beginning of the small intestine (duodenum)
nasogastric (NG) tube: tube inserted through the nose into the stomach
nasojejunal tube: tube inserted through the nose into the second portion of the small intestine (jejunum)
osmolality: ionic concentration of fluid osmosis: passage of solvent through a semipermeable membrane; the solvent, usually water, passes through the membrane from a region of low concentration of solute to that of a higher concentration of solute
parenteral nutrition: method of supplying nutrients to the body by an intravenous route
percutaneous endoscopic gastrostomy (PEG): an endoscopic procedure for placing a permanent feeding tube into the stomach
peristalsis: wavelike movement that occurs involuntarily in the alimentary canal
pH: the degree of acidity or alkalinity of a substance or solution
peripherally inserted central catheter (PICC): a device used for intermediate-term intravenous therapy
stoma: artificially created opening between a body cavity (eg, intestine) and the body surface
total nutrient admixture: an admixture of lipid emulsions, proteins, carbohydrates, electrolytes, vitamins, trace minerals, and water

**Gastric Sump**

The gastric sump (Salem) tube is a radiopaque, clear plastic, double-lumen NG tube used to decompress the stomach and keep it empty. It is 120 cm (48 in) long and is passed into the stomach in the same way as the Levin tube. The inner, smaller tube vents the larger suction-drainage tube to the atmosphere by means of an opening at the distal end of the tube. The sump tube can protect gastric suture lines because, when used properly, it maintains the force of suction at the drainage openings, or outlets, at less than 25 mm Hg, the level of capillary fragility. The small vent tube (known as the blue pigtail) controls this action. These tubes are connected to low continuous suction. The suction lumen is irrigated as prescribed to maintain patency.

To prevent reflux of gastric contents through the vent lumen (blue pigtail), the vent lumen is kept above the patient’s waist; otherwise it will act as a siphon. A one-way antireflux valve seated in the blue pigtail prevents the reflux of gastric contents out the vent lumen (Fig. 36-1). The valve is removed after irrigation of the suction lumen, and 20 mL of air is injected to reestablish a buffer of air between the gastric contents and the valve.

**MEDIUM TUBES**

Medium-length nasoenteric tubes are used for feeding. Feeding tubes placed in the duodenum are 160 cm (60 in) long; feeding tubes placed in the jejunum (portion of the small intestine adjacent to the duodenum) are 175 cm (66 in) long. They can be inserted at the time of surgery or before surgery, by interventional radiologists assisted by fluoroscopy or at the bedside. If the tube is inserted at the bedside, placement is verified by radiography.

After insertion, the tip of the tube will initially be in the stomach; it usually takes 24 hours for the tube to pass through the stomach and into the intestines.

**NURSING ALERT** Having the patient lie on the right side facilitates passage, because gravity and peristaltic motion will move the weighted tube into the duodenum.

Polyurethane or silicone rubber feeding tubes have narrow diameters (6 to 12 Fr) and tungsten tips (rather than mercury-filled bags); some have a water-activated lubricant that makes it easier to insert the tube. The tubing may kink when a stylet is not used, particularly if the patient is uncooperative or unable to swallow. Feeding tubes with a stylet are inserted with caution in patients who are predisposed to esophageal puncture, such as elderly and frail patients with thin tissues. These tubes are advanced in the same way as an NG tube; that is, with the patient in Fowler’s position. If this is not feasible, the patient is placed on the right side.

**LONG TUBES**

A long nasoenteric tube is introduced through the nose and passed through the esophagus and stomach into the intestinal tract. It is used to aspirate intestinal contents so that gas and fluid do not distend the intestine; this is called decompression. Three major nasoenteric tubes used for aspiration and decompression are the Miller-Abbott tube, the Harris tube, and the Cantor tube. These tubes are used to relieve obstruction of the small intestine. They are also used prophylactically; they may be inserted the night before GI surgery to prevent postoperative obstruction.
Because peristalsis is either stopped or slowed for 24 to 48 hours after surgery as a result of anesthesia and visceral manipulation, NG or nasoenteric suction is used to evacuate fluids and flatus so that vomiting is prevented, tension is reduced along the incision line, and obstruction is prevented. Usually, the tube remains in place until peristalsis returns, as evidenced by the resumption of bowel sounds and the passage of flatus.

**Miller-Abbott Tube**

The Miller-Abbott tube is a double-lumen rubber tube that is 300 cm (10 ft) long and 12, 14, 16, or 18 Fr in size. One lumen is used to introduce mercury, water, or saline into the balloon at the end of the tube for weighting of the tube; the other lumen is used for aspiration. Before the tube is inserted, the balloon should be tested and its capacity measured; then it should be deflated completely. The tube should be lubricated sparingly and chilled well (chilling causes the tube to become stiff and facilitates its passage) before the tip is inserted through the patient’s nose. Markings on the tube indicate the distance it has been passed. Before removal, the balloon at the end of the lumen must be completely deflated.

**Harris Tube**

The Harris tube is a single-lumen (14 Fr), mercury-weighted tube of about 180 cm (6 ft). This tube has a metal tip that is lubricated and introduced through the nose. The mercury-weighted bag follows. The weight of the mercury promotes the passage of the bag by gravity. This tube is used solely for suction and irrigation. Usually, a Y-tube is attached to the end of the Harris tube. The suction is applied to one side of the Y and the other side is clamped, except when irrigation of the tube is being performed.

**Cantor Tube**

The Cantor tube is 300 cm (10 ft) long and has a 16-Fr lumen. Its distinguishing feature is that it is larger than the other long tubes. It has a 4- or 5-ml bag at the extreme end of the rubber tubing; mercury, water or saline is introduced into this bag to weight the tube. Before the tube is inserted, the bag is wrapped around the tube. After the tube is lubricated, it is advanced through the nose and into the esophagus (Fig. 36-2). The patient assumes a sitting position and may be offered sips of water to facilitate passage of the tube. Fluoroscopy helps to verify that the tube has passed into the duodenum.

**NURSING MANAGEMENT OF PATIENTS UNDERGOING NASOGASTRIC OR NASOENTERIC INTUBATION**

Nursing interventions include the following:

- Instructing the patient about the purpose of the tube and the procedure required for inserting and advancing it
- Describing the sensations to be expected during tube insertion
- Inserting the NG tube and assisting with insertion of the nasoenteric tube
- Confirming the placement of the NG tube
- Advancing the nasoenteric tube
- Monitoring the patient and maintaining tube function
- Providing oral and nasal hygiene and care
- Monitoring for potential complications
- Removing the tube

**Providing Instruction**

Before the patient is intubated, the nurse explains the purpose of the tube; this information may assist the patient to be cooperative and tolerant of what is often an unpleasant procedure. The general activities related to inserting the tube are then reviewed, including the fact that the patient may have to breathe through the mouth and that the procedure may cause gagging until the tube has passed the area of the gag reflex.

**Inserting the Tube**

Before inserting the tube, the clinician determines how much tubing will be needed to reach the stomach or the small intestine. A mark is made on the tube to indicate the desired length. This length is determined by measuring the distance from the tip of the nose to the earlobe, and from the earlobe to the xiphoid process, then adding 6 inches for NG placement or 8 to 10 inches for intestinal placement (Fig. 36-3).

While the tube is being inserted, the patient usually sits upright with a towel spread bib-fashion over the chest. Tissue wipes are made available. Privacy and adequate light are provided. The physician may swab the nostril and spray the oropharynx with
FIGURE 36-2 Passage of Cantor tube. (A) Tube with weighted bag (mercury, water, normal saline solution) is introduced through the nose. (B) After the weighted bag has entered the nostril, the catheter is tilted upward (head can also be tilted slightly upward) to facilitate gravity pull on the weighted bag. (C) The weight of the mercury (or water or normal saline solution) pulls the bag downward.

1. Mark the nasogastric tube at a point 50 cm from the distal tip; call this point ‘A’.

2. Have the patient sit in a neutral position with head facing forward. Place the distal tip of the tubing at the tip of the patient’s nose (N); extend tube to the tragus (tip) of the ear (E), and then extend the tube straight down to the tip of the xiphoid (X). Mark this point ‘B’ on the tubing.

3. To locate point ‘C’ on the tube, find the midpoint between points A and B. The nasogastric tube is passed to point C to ensure optimum placement in the stomach.

FIGURE 36-3 Measuring length of nasogastric tube for placement into stomach.
Confirming Placement

To ensure patient safety, it is essential to confirm that the tube has been placed correctly, particularly because tubes may be accidentally inserted in the lungs, which may be undetected in high-risk patients. Examples of high-risk patients are those with a decreased level of consciousness, confused mental state, poor or absent cough and gag reflexes, or agitation during insertion. Presence of an endotracheal tube and recent removal of an endotracheal tube also increase the risk for inadvertent placement of the tube in the lung (Metheny, 1998). Initially, an x-ray study should confirm tube placement. However, each time liquids or medications are administered, and once a shift for continuous feedings, the tube must be checked to ensure that it remains properly placed. The traditional recommendation has been to inject air through the tube while auscultating the epigastric area with a stethoscope to detect air insufflations. However, studies indicate that this auscultatory method is not accurate in determining whether the tube has been inserted into the stomach, intestines, or respiratory tract (Metheny et al., 1999). Instead of the auscultation method, a combination of three methods is recommended:

- Measurement of tube length
- Visual assessment of aspirate
- pH measurement of aspirate

After the tube is inserted, the exposed portion of the tube is measured and the length is documented. The nurse measures the exposed tube length every shift and compares it with the original measurement. An increase in the length of exposed tube may indicate dislodgement, or a leaking or ruptured balloon if the tube has a balloon.

Visual assessment of the color of the aspirate may help identify tube placement. Metheny et al. (1994) found that gastric aspirate is most frequently cloudy and green, tan or off-white, or bloody or brown. Intestinal aspirate is primarily clear and yellow to bile-colored. Pleural fluid is usually pale yellow and serous, and tracheobronchial secretions are usually tan or off-white mucus. Researchers suggest that the appearance of the aspirate may be helpful in distinguishing between gastric and intestinal placement but is of little value in ruling out respiratory placement. This method is less helpful when the patient is receiving continuous feedings, because aspirate often looks like the formula that is used for the feeding (Metheny & Titler, 2001).

Determining the pH of the tube aspirate is a more accurate method of confirming tube placement. The pH method can also be used to monitor the advancement of the tube into the small intestines. The pH of gastric aspirate is acidic (1 to 5). The pH of intestinal aspirate is approximately 6 or greater, and the pH of respiratory aspirate is more alkaline (7 or greater). pH testing is best suited for distinguishing between gastric and intestinal placement. A pH sensor enteral tube is available which does not require fluid aspirate to obtain pH values; it can be useful in distinguishing gastric from small bowel placement of the tube. The pH method is less helpful with continuous feedings, because tube feedings have a pH value of 6.6 and neutralize the GI pH (Metheny & Titler, 2001). For more information, see Nursing Research Profile 36-1.

Using gastric aspiration as a means of verifying that the NG tube has been placed correctly may be a problem because of the characteristic properties and diameter of the tubes. Studies suggest that aspiration may be performed more easily with polyurethane tubes and tubes with a size 10 Fr diameter. Metheny et al. (1993) recommended the following steps if problems occur with aspiration of fluid from small-bore feeding tubes:

1. Insufflate 20 mL of air through the tube with a large syringe (30 to 60 mL).
2. Pull back on the plunger.
3. If step 2 is ineffective, insufflate another 20 mL of air and replace the large syringe with a smaller one (12 mL); attempt to aspirate.
4. If the measure is still ineffective, repeat step 3.
5. Change the patient’s position and attempt to aspirate.

Securing the Tube

After the correct position of the tip has been confirmed, the NG tube is secured to the nose (Fig. 36-4). A liquid skin barrier should be applied to the skin where the NG tube will be secured. The prepared area is covered with a strip of hypoallergenic tape or Op-site; the tube is then placed over the tape and secured with a second piece of tape. The nasoenteric tube can be secured by taping it to the forehead (see Fig. 36-4). This keeps the tube from dislodging when the patient moves but still allows it to pass into the intestine. Instead of tape, a feeding tube attachment device (Hollister) can be used to secure the tube. This device adheres to the nose and uses an adjustable clip to hold the tube in place (Fig. 36-5). After the nasoenteric tube has progressed into the intestine (after approximately 24 hours), the tube may be taped in place.

Advancing the Nasoenteric Decompression Tube

After the tube has passed through the pyloric sphincter, it may be advanced 5 to 7.5 cm (2 to 3 in) every hour. To enable gravity and peristalsis to assist in the passage of the tube, the patient is generally asked to lie in the following positions in this order: on the right side for 2 hours, on the back for 2 hours, and then on the left side for 2 hours. Ambulation, if possible, also helps advance the tube. If the tube is advanced too rapidly, it will curl and kink in the stomach. The tube is irrigated with normal saline solution every 6 to 8 hours to prevent blockage.
Assessment of Feeding Tube Location

Purpose
Although a wide variety of methods have been used to assess feeding tube location at the bedside, pH testing of aspirate has been found to be the most reliable in differentiating between gastric and respiratory placement of the tube and between gastric and intestinal placement of the tube. However, it is not reliable in distinguishing intestinal from respiratory fluids, because both of these fluids are alkaline. One new method that is being studied to distinguish these fluids is testing the tube aspirate for bilirubin, which is normally found in intestinal fluids but not in respiratory fluids.

The purposes of this study were (1) to assess the validity of a visual bilirubin test strip used with a colorimetric visual bilirubin (VBIL) scale to predict laboratory bilirubin values, (2) to evaluate the interrater reliability of staff nurses using the visual bilirubin test strip and VBIL scale, and (3) to evaluate the ability of the visual bilirubin test strip and VBIL scale in combination with pH testing to predict feeding tube placement in the respiratory tract, stomach, or intestine.

Study Sample and Design
Concurrent pH and bilirubin testing was conducted on 631 GI specimens obtained from adult, acutely ill patients with newly inserted feeding tubes; the testing was done within 5 minutes of x-ray studies obtained to confirm tube placement. Also, 225 respiratory specimens were tested. A test strip and VBIL scale as well as laboratory assay were used to measure bilirubin. A pH meter and pH test strips were used to measure pH. Results were read by research assistants and staff nurses, who were blinded to (unaware of) the source or type of specimens. These readings were compared with the x-ray results.

Findings
There was a high correlation (0.93) between the readings made from the VBIL scale and the laboratory bilirubin assay. A pH reading greater than 5 and a bilirubin reading lower than 5 mg/dL accurately identified 100% of the respiratory specimens. A pH of 5 or less and a bilirubin concentration lower than 5 mg/dL accurately identified 98% of the gastric specimens. Approximately 88% of the specimens with a pH greater than 5 and a bilirubin value of 5 mg/dL or higher were intestinal specimens.

Nursing Implications
Use of the VBIL scale and bilirubin test strip has the potential for greatly improving the accuracy of determining feeding tube placement at the bedside. However, before its approval by the U.S. Food and Drug Administration for this purpose, further refinements are required to make sure that the most accurate readings can be made. Until such approval, nurses must rely on the auscultatory method, pH measurements, and observations of the patient’s physical status to determine tube placement. Any question about correct tube placement should be investigated, and placement should be confirmed by x-ray studies whenever indicated.

FIGURE 36-4 Securing NG and nasoenteric tubes. (A) The NG tube is secured to the nose with tape to prevent injury to the nasopharyngeal passages. (B) Tape is placed on the forehead and the nasoenteric tube is taped to it, thereby allowing the tube to be advanced until desired placement is achieved. (C, D) Secure tubing to the patient’s gown with either an elastic band or tape attached to a safety pin to prevent tension on the line during movement of the patient.
inspected for skin irritation. If the nasal and pharyngeal mucosa are
abraded or traumatized, they may be in place for several days. Moistened cotton-tipped swabs
may be used to clean the nose, followed by cleansing with a water-
soluble lubricant. Frequent mouth care is comforting for the pa-

tient. The nasal tape is changed every 2 to 3 days, and the nose is
mucous membranes moist and help prevent inflammation of the parotid glands.

Monitoring and Maintaining Tube Function

If the NG tube is used for decompression, it is attached to inter-
mittent low suction. If it is used for enteral nutrition, the end of
the tube is plugged between feedings. The nurse confirms
tube placement before any fluids or medications are instilled and
once a shift for continuous feedings. Displacement of the

tube may be caused by tension on the tube (when the patient
moves around in the bed or room), coughing, tracheal or naso-
tracheal suctioning, or airway intubation. If the NG tube is re-
moved inadvertently in a patient who has undergone esophageal
or gastric surgery, it is replaced by the physician, usually under
fluoroscopy to avoid trauma to the suture line.

It is important to keep an accurate record of all fluid intake,
feedings, and irrigation. To maintain patency, the tube is irri-
gated every 4 to 6 hours with normal saline to avoid electrolyte
loss through gastric drainage. If an automatic flush enteral
pump is used, the flushing schedule may be altered. The nurse
records the amount, color, and type of all drainage every 8

hours.

When double- or triple-lumen tubes are used, each lumen is
labeled according to its intended use: aspiration, feeding, or bal-
loon inflation. To avoid tension on the tube, the portion of the
tube from the nose to the drainage unit is fixed in position, either
with a safety pin or with adhesive tape loops that are pinned to
the patient’s pajamas or gown. The tube must be looped loosely
to prevent tension and dislodgement (see Fig. 36-4).

Providing Oral and Nasal Hygiene

Regular and conscientious oral and nasal hygiene is a vital part of
patient care, because the tube causes discomfort and pressure and
may be in place for several days. Moistened cotton-tipped swabs
can be used to clean the nose, followed by cleansing with a water-
soluble lubricant. Frequent mouth care is comforting for the pa-

tient. The nasal tape is changed every 2 to 3 days, and the nose is
inspected for skin irritation. If the nasal and pharyngeal mucosa are

excessively dry, steam or cool vapor inhalations may be beneficial.
Throat lozenges, an ice collar, chewing gum, or sucking on hard
candies (if permitted), and frequent movement also assist in reliev-
ing patient discomfort. These activities keep the mucous mem-

branes moist and help prevent inflammation of the parotid glands.

Removing the Tube

Before removing a tube, the nurse may intermittently clamp and
unclamp the NG tube for a trial period of 24 hours to ensure that
the patient does not experience nausea, vomiting, or distention.
Before the tube is removed, it is flushed with 10 mL of normal
saline to ensure that it is free of debris and away from the gastric
lining; then the balloon (if present) is deflated. Gloves are worn
to remove the tube. The tube is withdrawn gently and slowly for
15 to 20 cm (6 to 8 in) until the tip reaches the esophagus; the

Patients with NG or nasoenteric intubation are susceptible to a
variety of problems, including fluid volume deficit, pulmonary
complications, and tube-related irritations. These potential com-

plications require careful ongoing assessment.

Symptoms of fluid volume deficit include dry skin and mucous membranes, decreased urinary output, lethargy, and decreased
body temperature. Assessment of fluid volume deficit involves
maintaining an accurate record of intake and output. This in-
cludes measuring NG drainage, fluid instilled by irrigation of the
NG tube, water taken by mouth, vomitus, water administered
with tube feedings, and intravenous (IV) fluids. Laboratory values,
particularly blood urea nitrogen and creatinine, are monitored.
The nurse assesses 24-hour fluid balance and reports negative
fluid balance, increased NG output, interruption of IV therapy,
or any other disturbance in fluid intake or output.

Pulmonary complications from NG intubation occur because
coughing and clearing of the pharynx are impaired, because gas
buildup can irritate the phrenic nerve, and because tubes may
become dislodged, retracting the distal end above the esopha-
gogastric sphincter. Medications (antacids, simethicone, and
metoclopramide) are administered to decrease potential prob-
lems. Signs and symptoms of complications include coughing
during the administration of foods or medications, difficulty
clearing the airway, tachypnea, and fever. Assessment includes
regular auscultation of lung sounds and routine assessment of
vital signs. It is important to encourage the patient to cough and
to take deep breaths regularly. The nurse also carefully confirms
the proper placement of the tube before instilling any fluids or
medications.

Irritation of the mucous membranes is a common complica-
tion of NG intubation. The nostrils, oral mucosa, esophagus, and
trachea are susceptible to irritation and necrosis. Visible areas are
inspected frequently, and the adequacy of hydration is assessed.
When providing oral hygiene, the nurse carefully inspects the
mucous membranes for signs of irritation or excessive dryness.
The nurse palpates the area around the parotid glands to detect
any tenderness or enlarged nodes, indicating parotitis, and ob-
serves for any skin or mucous membrane irritation or necrosis. In
addition, it is important to assess the patient for esophagitis and
tracheitis; symptoms include sore throat and hoarseness.
remainder is withdrawn rapidly from the nostril. A nasointestinal tube is withdrawn at intervals of 10 minutes until the end reaches the esophagus. If the tube does not come out easily, force should not be used, and the problem should be reported to the physician. As the tube is withdrawn, it is concealed in a towel, because the sight of it may be unpleasant to the patient. After the tube is removed, the nurse provides oral hygiene.

As the tube is withdrawn, it is concealed in a towel, because the sight of it may be unpleasant to the patient. After the tube is removed, the nurse provides oral hygiene.

**Tube Feedings With Nasogastric and Nasoenteric Devices**

Tube feedings are given to meet nutritional requirements when oral intake is inadequate or not possible and the GI tract is functioning normally. Tube feedings have several advantages over parenteral nutrition: they are low in cost, safe, well tolerated by the patient, and easy to use both in extended care facilities and in the patient’s home. Tube feedings have other advantages:

- They preserve GI integrity by delivery of nutrients and medications (antacids, simethicone, and metoclopramide) intraluminally.
- They preserve the normal sequence of intestinal and hepatic metabolism.
- They maintain fat metabolism and lipoprotein synthesis.
- They maintain normal insulin/glucagon ratios.

Tube feedings are delivered to the stomach (in the case of NG intubation or gastrostomy) or to the distal duodenum or proximal jejunum (in the case of nasoduodenal or nasojejunal tube feeding). Nasoduodenal or nasojejunal feeding is indicated when the esophagus and stomach need to be bypassed or when the patient is at risk for aspiration (breathing fluids or foods into the trachea and lungs). For long-term feedings (longer than 4 weeks), nasoduodenal, gastrostomy, or jejunostomy tubes are preferred for administration of medications or food. The numerous conditions requiring enteral nutrition are summarized in Table 36-2.

**OSMOSIS AND OSMOLALITY**

Osmolality is an important consideration for patients receiving tube feedings through the duodenum or jejunum, because feeding formulas with a high osmolality may lead to undesirable effects, such as dumping syndrome (described below).

Fluid balance is maintained by osmosis, the process by which water moves through membranes from a dilute solution of lower osmolality (ionic concentration) to a more concentrated solution of higher osmolality until both solutions are of nearly equal osmolality. The osmolality of normal body fluids is approximately 300 mOsm/kg. The body attempts to keep the osmolality of the contents of the stomach and intestines at approximately this level.

Highly concentrated solutions and certain foods can upset the normal fluid balance in the body. Individual amino acids and carbohydrates are small particles that have great osmotic effect. Proteins are extremely large particles and therefore have less osmotic effect. Fats are not water-soluble and do not enter into a solution in water; thus, they have no osmotic effect. Electrolytes, such as sodium and potassium, are comparatively small particles; they have a great effect on osmolality and consequently on the patient’s ability to tolerate a given solution.

When a concentrated solution of high osmolality is taken in large amounts, water will move to the stomach and intestines from fluid surrounding the organs and the vascular compartment. The patient has a feeling of fullness, nausea, and diarrhea; this causes dehydration, hypotension, and tachycardia, collectively termed the *dumping syndrome*. Starting with a more dilute solution and increasing the concentration over several days can generally alleviate this problem. Patients vary in the degree to which they tolerate the effects of high osmolality; usually debilitated patients are more sensitive. The nurse needs to be knowledgeable about the osmolality of the patient’s formula and needs to observe for and take steps to prevent undesired effects.

**TUBE FEEDING FORMULAS**

The choice of formula to be delivered by tube feeding is influenced by the status of the GI tract and the nutritional needs of

*Because some of these patients are at risk for regurgitating or vomiting and aspirating administered formula, each condition must be considered individually.*
the patient. The formula characteristics evaluated include chemical composition of the nutrient source (protein, carbohydrates, fat), caloric density, osmolality, residue, bacteriologic safety, vitamins, minerals, and cost.

Various major formula types for tube feedings are available commercially. Blended formulas can be made by the patient’s family or obtained in a ready-to-use form that is carefully prepared according to directions. Commerically prepared polymeric formulas (formulas with high molecular weight) are composed of protein, carbohydrates, and fats in a high-molecular-weight form (Boost Plus, TwoCal HN, Isosource). Chemically defined formulas contain predigested and easy-to-absorb nutrients (Osmolite HN). Modular products contain only one major nutrient, such as protein (Promote). Disease-specific formulas are available for various conditions, such as renal failure (Nepro), severe chronic obstructive pulmonary disease (Pulmocare). Nepro is high in calories and low in electrolytes. It is ideal for patients who require electrolyte and fluid restriction. Pulmocare is high in fat and low in carbohydrates. Its high density (1.5 calories/mL) is ideal for patients who require fluid restriction, and it is also designed to reduce carbon dioxide production. Fiber has also been added to formulas (Jevity) in an attempt to decrease the occurrence of diarrhea. Some feedings are given as supplements, and others are designed to meet the patient’s total nutritional needs. Dietitians collaborate with physicians and nurses in determining the best formula for the individual patient.

**NURSING ALERT** Commercial formulas frequently present problems because the composition is fixed and some patients are not able to tolerate certain ingredients, such as sodium, protein, or potassium. Modular products may be substituted, and the critical constituents of sodium, potassium, and fat can be added. Attention is given to including all essential minerals and vitamins. Total intake of calories, nutrients, and fluids must be assessed when there is a reduction in total intake or excessive dilution of feedings.

**TUBE FEEDING ADMINISTRATION METHODS**

Many patients do not tolerate NG and nasoenteric tube feedings well. Often a medium- or fine-bore Silastic nasoenteric tube is tolerated better than a plastic or rubber tube. The finer-bore tube requires a finely dispersed formula to ensure that the patency of the tube is maintained. For long-term tube feeding therapy, a gastrostomy or jejunostomy tube is used (see later discussion).

The tube feeding method chosen depends on the location of the tube, patient tolerance, convenience, and cost. Intermittent bolus feedings are administered into the stomach (usually by gastrostomy tube) in large amounts at designated intervals and may be given 4 to 8 times per day. The intermittent gravity drip is another method for administering tube feedings into the stomach and is commonly used when the patient is at home. In this instance, the tube feeding is administered over 30 minutes at designated intervals. Both of these tube-feeding methods are practical and inexpensive. However, the feedings delivered at variable rates may be poorly tolerated and time-consuming.

The continuous infusion method is used when feedings are administered into the small intestine. This method is preferred for patients who are at risk for aspiration or who tolerate the tube feedings poorly. The feedings are given continuously at a constant rate by means of a pump. The continuous tube feeding method, which requires a pump device, decreases abdominal distention, gastric residuals, and the risk of aspiration. However, pumps are expensive, and they permit the patient less flexibility than intermittent feedings do.

An alternative to the continuous infusion method is cyclic feeding. The infusion is given at a faster rate over a shorter time (usually 8 to 12 hours). Feeding may be infused at night to avoid interrupting the patient’s lifestyle. Cyclic continuous infusions may be appropriate for patients who are being weaned from tube feedings to an oral diet, as a supplement for a patient who cannot eat enough, and for patients at home who need daytime hours free from the pump.

Tube feeding solutions vary in terms of required preparation, consistency, and the number of calories and supplemental vitamins they contain. The choice of solution depends on the size and location of the tube, the patient’s nutrient needs, the type of nutritional supplement, the method of delivery, and the convenience for the patient at home. A wide variety of containers, feeding tubes and catheters, delivery systems, and pumps are available for use with tube feedings.

**NURSING PROCESS: THE PATIENT RECEIVING A TUBE FEEDING**

**Assessment**

A preliminary assessment of the patient who requires a tube feeding includes several considerations, as well as the family’s need for information:

- What is the patient’s nutritional status, as judged by current physical appearance, dietary history, and recent weight loss?
- Are there any existing chronic illnesses or factors that will increase metabolic demands on the body (eg, surgical stress, fever)?
- What is the patient’s hydration status? What are the electrolyte levels?
- Is the patient’s digestive tract functioning?
- Are the kidneys functioning normally?
- Are fluid requirements (ie, 30 to 40 mL/kg body weight) being met?
- What medications and other therapies is the patient receiving that may affect digestive intake and function of the digestive system?
- Does the dietary prescription fulfill the patient’s needs?

In addition, a more elaborate assessment is performed for patients who require extensive nutritional therapy. A team that includes the nurse, physician, and dietitian conducts this assessment. In addition to the history and physical examination (which includes anthropometric measurements), nutritional assessment consists of recording any weight change; determining albumin, prealbumin, and transferrin levels and total lymphocyte count; testing for the delayed hypersensitivity reaction; and evaluating muscle function. (See Chapter 5 for a detailed description of nutritional assessment.)

**Diagnosis**

**NURSING DIAGNOSES**

Based on the assessment data, the major nursing diagnoses may include the following:
Residual gastric content is measured before each intermittent feeding and every 4 to 8 hours during continuous feedings. (This aspirated fluid is readministered to the patient.) The research findings of McClave et al. (1992) indicated that, if the amount of aspirated gastric content is greater than or equal to 200 mL for NG tubes or if residual volumes are greater than or equal to 100 mL for gastrostomy tubes, tube feeding intolerance should be considered. Tube feedings may be continued with close monitoring of gastric residual volume, radiographic studies, and the patient’s physical status. If excessive residual volumes occur twice, the nurse notifies the physician.

Maintaining tube function is an ongoing responsibility of the nurse, patient, or primary caregiver. To ensure patency and to decrease the chance of bacterial growth, crusting, or occlusion of the tube, 20 to 30 mL of water is administered in each of the following instances:

- Before and after each dose of medication and each tube feeding
- After checking for gastric residuals and gastric pH
- Every 4 to 6 hours with continuous feedings
- If the tube feeding is discontinued for any reason

### PROVIDING MEDICATIONS BY TUBE

When different types of medications are administered, each type is given separately, using a bolus method that is compatible with the medication’s preparation (Table 36-4). The tube is flushed with 20 to 30 mL of water after each dose. If a liquid form of a medication is not available and the medication can be crushed, it must first be reduced to a fine powder or the tube will become clogged. Devices are available (eg, Handicrush Irrigation Syringe by Nestle) that crush and dissolve tablets with water (Fig. 36-7). Medications are not mixed with each other or with the feeding formula. When small-bore feeding tubes for continuous infusion are irrigated after medication administration, a 30-mL or larger syringe is used, because the pressure generated by smaller syringes could rupture the tube.

### MAINTAINING FEEDING REGIMENS AND DELIVERY SYSTEMS

Tube feeding formula is delivered to patients by either an open or a closed system. The open system comes in cans or as a powder and may be mixed with water. The feeding container (which is hung on a pole) and the tubing used with the open system are changed—usually every 24 to 72 hours. To avoid bacterial contamination, the amount of feeding formula in the bag should never exceed what is expected to be infused in 4 hours.

Closed delivery systems use a prefilled, sterile container that is spiked with enteral tubing. The bag holding the feeding formula for the closed system can be hung safely for 24 to 48 hours.

The tube-feeding regimen must be assessed frequently to evaluate its effectiveness and avoid complications (Chart 36-1).

### MAINTAINING NORMAL BOWEL ELIMINATION PATTERN

Patients receiving NG or nasoenteric tube feedings commonly have diarrhea (watery stools occurring three or more times in 24 hours). Pasty, unformed stool is expected with enteral therapy, because many formulas have little or no residue. The dumping syndrome also leads to diarrhea, but to confirm dumping syndrome as the cause of diarrhea other possible causes must be ruled out, among them the following:

- Imbalanced nutrition, less than body requirements, related to inadequate intake of nutrients
- Risk for diarrhea related to the dumping syndrome or to tube feeding intolerance
- Risk for ineffective airway clearance related to aspiration of tube feeding
- Risk for deficient fluid volume related to hypertonic dehydration
- Risk for ineffective coping related to discomfort imposed by the presence of the NG or nasoenteric tube
- Risk for ineffective therapeutic regimen management
- Deficient knowledge about home tube feeding regimen

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Complications of NG and nasoenteric tube feeding therapy are classified into three types—GI, mechanical, and metabolic. Table 36-3 lists complications, possible causes, and appropriate interventions.

### Planning and Goals

The major goals for the patient may include nutritional balance, normal bowel elimination pattern, reduced risk of aspiration, adequate hydration, individual coping, knowledge and skill in self-care, and prevention of complications.

### Nursing Interventions

#### MAINTAINING FEEDING EQUIPMENT AND NUTRITIONAL BALANCE

The temperature and volume of the feeding, the flow rate, and the total fluid intake are important factors to be considered when tube feedings are administered. The schedule of tube feedings, including the correct quantity and frequency, is maintained. The nurse must carefully monitor the drip rate and avoid administering fluids too rapidly.

Feedings are administered by gravity (drip), bolus, or continuous controlled pump (mL/hour or drops/hour). Gravity feedings are placed above the level of the stomach, with the speed of administration determined by gravity. Bolus feedings are given in large volumes (300 to 400 mL every 4 to 6 hours). Continuous feeding is the preferred method; delivery of the feeding in small amounts over long periods reduces the incidence of aspiration, distention, nausea, vomiting, and diarrhea. Continuous administration rates of about 100 to 150 mL/hour (2400 to 3600 calories/day) are effective in inducing positive nitrogen balance and diarrhea. If the feeding is intermittent, 200 to 350 mL is given in 10 to 15 minutes. Enteral pumps are mechanical devices that control the delivery rate of feeding formula (Fig. 36-6). Pumps allow for a constant flow rate and can infuse a viscous formula through a small-diameter feeding tube. These pumps are relatively heavy and must be attached to an IV pole. For home use, there are portable lightweight enteral pumps available that weigh about 4 pounds and are easy to handle. An enteral pump is available with an automatic water flush system. In addition to administering the feeding formula, these pumps provide hourly water flushes that are designed to prevent clogged feeding tubes (Petnicki, 1998).

#### MAINTAINING FEEDING REGIMENS

The tube-feeding regimen must be assessed frequently to evaluate its effectiveness and avoid complications (Chart 36-1).
Zinc deficiency—Adding 15 mg of zinc to the tube feeding every 24 hours is recommended to maintain a normal serum level of 50 to 150 fg/dL (7.65 to 22.95 fmol/L).

Contaminated formula

Malnutrition—A decrease in the intestinal absorptive area resulting from malnutrition can cause diarrhea.

Medication therapy—Antibiotics, such as clindamycin (Cleocin) and lincomycin (Lincoln); antiarrhythmics, such as quinidine and propranolol (Inderal); and aminophylline, theophylline, and digitalis have been found to increase the frequency of diarrhea in some patients.

The dumping syndrome results from rapid distention of the jejunum when hypertonic solutions are administered quickly (over 10 to 20 minutes). Foods high in carbohydrates and electrolytes draw extracellular fluid from the vascular system into the jejunum so that dilution and absorption can occur. Measures for managing the GI symptoms (diarrhea, nausea) associated with the dumping syndrome are presented in Chart 36-2.

### REDUCING THE RISK OF ASPIRATION

Aspiration pneumonia occurs when stomach contents or enteral feedings are regurgitated and aspirated, or when an NG tube is improperly positioned and feedings are instilled into the pharynx or the trachea. Nasoenteric tubes, especially those that provide for gastric and esophageal or duodenal decompression, have helped decrease the frequency of regurgitation and aspiration.

![Chapter 36 Gastrointestinal Intubation and Special Nutritional Modalities](995)
To prevent aspiration, the nurse must establish the correct tube feeding placement before every feeding, each time medications are administered, and once every shift if the tube feeding is continuous. Feedings and medications should always be given with the patient in the proper position to prevent regurgitation. To reduce the risk of reflux and pulmonary aspiration, the semi-Fowler’s position is necessary for an NG feeding, with the patient’s head elevated at least 30 to 45 degrees. This position is maintained at least 1 hour after completion of an intermittent tube feeding and is maintained at all times for patients receiving continuous tube feedings. Another prevention strategy is to monitor residual volumes (Edwards & Metheny, 2000).

If aspiration is suspected, the feeding is stopped immediately, the pharynx and trachea are suctioned, and the patient is placed on the right side with the head of the bed down. The physician is notified immediately.

MAINTAINING ADEQUATE HYDRATION

The nurse carefully monitors hydration because, in many cases, the patient cannot communicate the need for water. Water (at least 2 L/day) is given every 4 to 6 hours and after feedings to prevent hypertonic dehydration. At the beginning of administration, the feeding is diluted to at least half-strength and not more than 50 to 100 mL is given at a time, or 40 to 60 mL/hour is given in continuous drip administration. This gradual administration helps the patient to develop tolerance, especially for hyperosmolar solutions. Key nursing interventions include observing for signs of dehydration (dry mucous membranes, thirst, decreased urine output); administering water routinely and as needed; and monitoring intake, output, and fluid balance (24-hour intake versus output).

that daily progressive improvement is possible. If the patient is age the patient to accept physical changes and to convey hope.

The psychosocial goal of nursing care is to support and encourage the patient to tolerate the formula. The Pill Crusher™ Syringe (from Welcon, Inc.) crushes medications to a fine powder and then allows them to be administered to persons with feeding tubes. The Pill Crusher™ is also used to irrigate the feeding tube and assists in hydrating the patient. Courtesy of Welcon, Inc., Fort Worth, TX (www.welcon.com).

PROMOTING COPING ABILITY

The psychosocial goal of nursing care is to support and encourage the patient to accept physical changes and to convey hope that daily progressive improvement is possible. If the patient is having difficulty adjusting to the treatment, the nurse intervenes by encouraging self-care (eg, recording daily weight and intake and output), within the parameters of the patient’s activity level. In addition, the nurse reinforces an optimistic approach by identifying signs and symptoms that indicate progress (daily weight gain, electrolyte balance, absence of nausea and diarrhea).

PROMOTING HOME AND COMMUNITY-BASED CARE

Teaching Patients Self-Care

Patients who require long-term tube feedings in the home care setting have conditions such as obstruction of the upper GI tract, malabsorption syndrome, surgery of the GI tract or of the head or neck region, or decreased level of consciousness. For a patient to be considered for tube feeding at home, the following criteria must be met: The patient must be medically stable and must have successfully completed a tube feeding trial (tolerated 70% of feeding). In addition, the patient must be capable of self-care or have a caregiver who is willing to assume the responsibility, and the patient or caregiver must have access to supplies and interest in learning how to administer tube feedings at home.

Preparation of the patient for home administration of enteral feedings begins while the patient is still hospitalized. Ideally, the nurse teaches while administering the feedings so that the patient can observe the mechanics of the procedure, participate in the procedure, ask questions, and express any concerns. Before discharge, the nurse provides information about the equipment needed, formula purchase and storage, and administration of the feedings (frequency, quantity, rate of instillation).

Family members who will be active in the patient’s home care are encouraged to participate in all teaching sessions. Available printed information about the equipment, the formula, and the procedure is reviewed. The nurse encourages the patient and caregiver to learn to use the equipment with the supervision of the nurse. Arrangements are made for the caregiver to obtain the equipment and formula and have it ready for use before the patient’s discharge.

Continuing Care

Referral to a home care agency is important so that a nurse can arrange to be present to supervise and provide support during the first feeding at home. Further visits will depend on the skill and comfort of the patient or caregiver in administering the feedings.

---

\textbf{Chart 36-1 • ASSESSMENT}

\begin{itemize}
  \item \textbf{Measures for Assessing Tube Feeding Regimens}
  \begin{itemize}
    \item 1. Assess tube placement, patient’s position (head of bed elevated 30 to 45 degrees), and formula flow rate.
    \item 2. Determine the patient’s ability to tolerate the formula. Observe for fullness, bloating, distention, urticaria, nausea, vomiting, and stool pattern and character.
    \item 3. Check clinical responses, as noted in laboratory findings (blood urea nitrogen, serum protein, prealbumin, electrolytes, renal function, hemoglobin, hematocrit).
    \item 4. Observe for signs of dehydration (dry mucous membranes, thirst, decreased urine output).
    \item 5. Record the amount of formula actually taken in by the patient.
    \item 6. Report an elevated blood glucose level, decreased urinary output, sudden weight gain, and periorbital or dependent edema.
    \item 7. Replace any formula administered by an open system every 4 hours with fresh formula. Formula should be at room temperature or cool (not cold).
    \item 8. Change tube feeding container and tubing every 24 to 72 hours.
    \item 9. Assess residual volume before each feeding or, in the case of continuous feedings, every 4 hours. Return the aspirate to the stomach.
    \item 10. Monitor intake and output.
    \item 11. Weigh the patient twice weekly.
    \item 12. Consult the dietitian regularly.
  \end{itemize}
\end{itemize}

\textbf{Figure 36-7} The Pill Crusher™ Syringe (from Welcon, Inc.) crushes medications to a fine powder and then allows them to be administered to persons with feeding tubes. The Pill Crusher™ is also used to irrigate the feeding tube and assists in hydrating the patient. Courtesy of Welcon, Inc., Fort Worth, TX (www.welcon.com).

\textbf{Chart 36-2 Preventing Symptoms of Dumping Syndrome}

The following strategies may help prevent some of the uncomfortable symptoms of dumping syndrome related to tube feeding:

- Slow the formula instillation rate to provide time for carbohydrates and electrolytes to be diluted.
- Administer feedings at room temperature, because temperature extremes stimulate peristalsis.
- Administer feeding by continuous drip (if tolerated) rather than by bolus, to prevent sudden distention of the intestine.
- Advise the patient to remain in semi-Fowler’s position for 1 hour after the feeding; this position prolongs intestinal transit time by decreasing the effect of gravity.
- Instill the minimal amount of water needed to flush the tubing before and after a feeding, because fluid given with a feeding increases intestinal transit time.

\textbf{Chapter 36 Gastrointestinal Intubation and Special Nutritional Modalities}
During all visits, the nurse monitors the patient’s physical status (weight, vital signs, activity level) and the ability of the patient and family to administer the tube feedings correctly. In addition, the nurse assesses for any complications (dumping syndrome, nausea or vomiting, weight loss, lethargy, confusion, excessive thirst). The patient or caregiver is encouraged to keep a diary to record times and amounts of feedings and any symptoms that occur. The nurse reviews the diary with the patient and caregiver during home visits.

**Evaluation**

**EXPECTED PATIENT OUTCOMES**

Expected patient outcomes may include the following:

1. Attains or maintains nutritional balance
   a. Has a positive nitrogen balance
   b. Maintains laboratory values within normal limits (ie, blood urea nitrogen, hemoglobin, hematocrit, prealbumin, serum protein)
   c. Attains or maintains hydration of body tissue
   d. Attains or maintains desired body weight
2. Is free of episodes of diarrhea
   a. Has fewer than three watery stools a day
   b. Does not have a bowel movement after a bolus feeding
   c. States that there is no intestinal cramping
   d. Has normal bowel sounds
3. Avoids aspiration
   a. Lungs are clear to auscultation
   b. Exhibits normal heart rate and respirations
4. Attains or maintains hydration of body tissue
   a. Has a balanced intake and output every 24 hours
   b. Does not have dry skin or dry mucous membranes
5. Copes effectively with tube feeding regimen
6. Demonstrates skill in managing tube feeding regimen
7. Experiences no complications
   a. Has no GI disturbances
   b. Tube remains intact and patent for duration of therapy
   c. Maintains metabolic balance within normal limits

**Gastrostomy**

A **gastrostomy** is a surgical procedure in which an opening is created into the stomach for the purpose of administering foods and fluids. In some instances, a gastrostomy is preferred for prolonged nutrition (greater than 3 to 4 weeks)—for example, in the elderly or debilitated patient. Gastrostomy is also preferred over NG feedings in the comatose patient because the gastroesophageal sphincter remains intact. Regurgitation and aspiration are less likely to occur with a gastrostomy than with NG feedings.

Different types of feeding gastrostomies may be used, including the Stamm (temporary and permanent), Janeway (permanent), and percutaneous endoscopic gastrostomy (temporary) systems. The Stamm and Janeway gastrostomies require either an upper abdominal midline incision or a left upper quadrant transverse incision. The Stamm procedure requires the use of concentric purse-string sutures to secure the tube to the anterior gastric wall. To create the gastrostomy, an exit wound is created in the left upper abdomen. The Janeway procedure necessitates the creation of a tunnel (called a gastric tube) that is brought out through the abdomen to form a permanent stoma.

A **percutaneous endoscopic gastrostomy (PEG)** is a procedure that requires the services of two physicians (or a physician and a nurse with specialty skills). After administering a local anesthetic, one physician inserts a cannula into the stomach through an abdominal incision and then threads a nonabsorbable suture through the cannula; the second physician looks through an endoscope that has been passed into the upper GI tract and uses the endoscopic snare to grasp the end of the suture and guide it up through the patient’s mouth. The suture is knotted to the dilator tip at the end of the PEG tube. The endoscopist then advances the dilator tip through the patient’s mouth while the first physician pulls the suture through the cannula site. The attached PEG tube is guided down the esophagus, into the stomach, and out through the abdominal incision (Fig. 36-8A). The mushroom catheter tip and internal crossbar secure the tube against the stomach wall. An external crossbar or bumper keeps the catheter.
in place. A tubing adaptor is in place between feedings, and a clamp or plug is used to close or open the tubing. If an endoscope is unable to pass through the esophagus, then the gastrostomy can be performed under x-ray guidance through the abdominal wall. This procedure is known as fluoroscopically guided percutaneous gastrostomy, or FGPG (Johnson, 1997).

The initial PEG device can be removed and replaced once the tract is well established (10 to 14 days after insertion). Replacement of the PEG device is indicated to provide long-term nutritional support, to replace a clotted or migrated tube, or to enhance patient comfort. The PEG replacement device should be fitted securely to the stoma to prevent leakage of gastric acid and is maintained in place through traction between the internal and anchoring devices.

An alternative to the PEG device is a low-profile gastrostomy device (LPGD) (see Fig. 36-8B). The LPGD may be inserted 3 to 6 months after initial gastrostomy tube placement. These devices are inserted flush with the skin; they eliminate the possibility of tube migration and obstruction and have antireflux valves to prevent gastric reflux. Two types of devices may be used—obturated or nonobturated. The obturated devices (G-button) have a dome tip that acts as an internal stabilizer. A major drawback is the need for a physician to obturate (insert a tube that is larger than the actual stoma). The nonobturated device (MIC-KEY) has an external skin disk and is inserted into the stoma without force; a balloon is inflated to secure placement. A nurse in the home setting can insert these devices easily. The drawbacks of both types of LPGDs are the inability to check residual volumes (one-way valve) and the need for a special adaptor to connect the device to the feeding container.

Patients with severe gastroesophageal reflux are at risk for aspiration pneumonia and therefore are not candidates for a gastrostomy. A jejunostomy is preferred, or jejunal feeding through a nasojejunal tube may be recommended.

**NURSING PROCESS: THE PATIENT WITH A GASTROSTOMY**

**Assessment**

The focus of the preoperative assessment is to determine the patient’s ability both to understand and to cope with the impending surgical experience. The nurse evaluates the patient’s ability to adjust to a change in body image and to participate in self-care, along with the patient’s and the family’s psychological status.

The purpose of the operative procedure is explained so that the patient will have a better understanding of the expected postoperative course. The patient needs to know that the result of this surgery is to bypass the mouth and esophagus so that liquid feedings can be administered directly into the stomach by means of a rubber or plastic tube or a prosthesis. If the prosthesis is to be permanent, the patient should be made aware of this. Psychologically, this is often difficult for the patient to accept. If the procedure is being performed to relieve discomfort, prolonged vomiting, debilitation, or an inability to eat, the patient may find it more acceptable.

The nurse evaluates the patient’s skin condition and determines whether a delay in healing may be anticipated because of a systemic disorder (eg, diabetes mellitus, cancer).

In the postoperative period, the patient’s fluid and nutritional needs are assessed to ensure proper intake of food and fluids. The nurse inspects the tube for proper maintenance and the incision for signs of infection. At the same time, the nurse evaluates the patient’s response to the change in body image and the patient’s understanding of the feeding methods. Interventions are identified to help the patient cope with the tube and learn self-care measures.

**Diagnosis**

**NURSING DIAGNOSES**

Based on the assessment data, the major nursing diagnoses in the postoperative period may include the following:

- Imbalanced nutrition, less than body requirements, related to enteral feeding problems
- Risk for infection related to presence of wound and tube
- Risk for impaired skin integrity at tube site
- Ineffective coping related to inability to eat normally
- Disturbed body image related to presence of tube
- Risk for ineffective therapeutic regimen management related to knowledge deficit about home care and the feeding procedure

**COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS**

Potential complications that may develop include the following:

- Wound infection, cellulitis, and abdominal wall abscess
- GI bleeding
- Premature removal of the tube

**Planning and Goals**

The major goals for the patient may include attaining an optimal level of nutrition, preventing infection, maintaining skin integrity, enhancing coping, adjusting to changes in body image, acquiring knowledge of and skill in self-care, and preventing complications.

**Nursing Interventions**

**MEETING NUTRITIONAL NEEDS**

The first fluid nourishment is administered soon after surgery and usually consists of tap water and 10% glucose. At first, only 30 to 60 mL (1 to 2 oz) is given at one time, but the amount is increased gradually. By the second day, 180 to 240 mL (6 to 8 oz) may be given at one time, provided it is tolerated and no leakage of fluid occurs around the tube. Water and milk can be instilled after 24 hours for a permanent gastrostomy. High-calorie liquids are added gradually. In some settings, during the early postoperative period the nurse aspirates gastric secretions and reinstills them after adding enough feeding solution to bring the volume to the desired total. By this method, gastric dilution is avoided.

Blenderized foods are added gradually to clear liquids until a full diet is achieved. Powdered feedings that are easily liquefied are commercially available. The patient who receives blenderized tube feedings typically is not forced to give up usual dietary patterns, which may prove to be psychologically more acceptable. In addition, near-normal bowel function is promoted because the fiber and residue are similar to that of a normal diet. Intake of milk is avoided in patients with lactase deficiency.

**PROVIDING TUBE CARE AND PREVENTING INFECTION**

A small dressing can be applied over the tube outlet, and the gastrostomy tube can be held in place by a thin strip of adhesive tape that is first placed around the tube and then firmly attached to
the abdomen. The dressing protects the skin around the incision from seepage of gastric acid and spillage of feedings.

The nurse verifies the tube’s placement, assesses residuals, and rotates the tube or stabilizing disk once daily to prevent skin breakdown. Some gastrostomy tubes have balloons that are inflated with water to anchor the tube in the stomach. The adequacy of balloon inflation is checked weekly by deflating the balloon using a Luer-tip syringe.

PROVIDING SKIN CARE

The skin surrounding a gastrostomy requires special care because it may become irritated from the enzymatic action of gastric juices that leak around the tube. Left untreated, the skin becomes macerated, red, raw, and painful. The nurse washes the area around the tube with soap and water daily, removes any encrustation with saline solution, rinses the area well with water, and pats it dry. Once the stoma heals and drainage ceases, a dressing is not required. A long-term gastrostomy may require a special dressing or stabilization device to protect the skin around the tube from gastric secretions and to help secure the tube in place (Fig. 36-9).

Skin at the exit site is evaluated daily for signs of breakdown, irritation, excoriation, and the presence of drainage or gastric leakage. The nurse encourages the patient and family members to participate in this inspection and in hygiene activities. If skin problems do occur, an enterostomal therapist or wound care specialist can be of assistance.

ENHANCING BODY IMAGE

The patient with a gastrostomy has experienced a major assault to body image. Eating, a physiologic and social function, can no longer be taken for granted. The patient is also aware that gastrostomy as a therapeutic intervention is performed only in the presence of a major, chronic, or perhaps terminal illness.

Calm discussion of the purposes and routines of gastrostomy feeding can help keep the patient from feeling overwhelmed. Talking with a person who has had a gastrostomy can also help the patient to accept the expected changes. Adjusting to a change in body image takes time and requires family support and acceptance. Evaluating the existing family support system is necessary. One family member may emerge as the primary support person.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

During the postoperative course, the nurse monitors the patient for potential complications. The most common complications are wound infection and other wound problems, including cellulitis at the wound site and abscesses in the abdominal wall. Because many patients who receive tube feedings are debilitated and have compromised nutritional status, any signs of infections are promptly reported to the physician so that appropriate antibiotic therapy can be instituted.

Bleeding from the insertion site in the stomach may also occur. The nurse closely monitors the patient’s vital signs and observes all drainage from the operative site, vomitus, and stool for evidence of bleeding. Any signs of bleeding are reported promptly.

Premature removal of the tube, whether it is done inadvertently by the patient or by the caregiver, is another complication. If the tube is removed prematurely, the skin is cleansed and a sterile dressing is applied; the nurse immediately notifies the physician. The tract will close within 4 to 6 hours if the tube is not replaced promptly.

PROMOTING HOME AND COMMUNITY-BASED CARE

Teaching Patients Self-Care

The patient who is to receive gastrostomy tube feedings in the home setting must be capable of, and responsible for, administering the tube feedings or have a caregiver who is able to do so. There must also be the physical, financial, and social resources to maintain care.

The nurse assesses the patient’s level of knowledge, interest in learning about the tube feeding, and ability to understand and apply the information before providing detailed instructions about how to prepare the formula and manage the tube feeding. Written materials for patients and caregivers are designed to outline the care instructions. To facilitate self-care, the nurse encourages the patient to participate in the tube feedings during hospitalization and to establish as normal a routine as possible.

Demonstration of the tube feeding begins by showing the patient how to check for residual gastric contents before the feeding. The patient then learns how to check and maintain the patency of the tube by administering room-temperature water before and after the feeding. This will establish patency before the feeding and then clear the tube of food particles, which could decompose if allowed to remain in the tube. All feedings are given at room temperature or near body temperature.

For a bolus feeding, the nurse shows the patient how to introduce the liquid into the catheter by using a funnel or the barrel of a syringe. The receptacle is tilted to allow air to escape while the liquid is being instilled initially. As the funnel or syringe fills with liquid, the feeding is allowed to flow into the stomach by gravity, holding the barrel or syringe perpendicular to the abdomen (Fig. 36-10). Raising or lowering the receptacle to no higher than 45 cm (18 in) above the abdominal wall regulates the rate of flow.

A bolus feeding of 300 to 500 mL usually is given for each meal and requires 10 to 15 minutes to complete. The amount is often determined by the patient’s reaction. If the patient feels full, it may be desirable to give smaller amounts more frequently.

The patient and caregiver must understand that keeping the head of the bed elevated for at least 1 hour after feeding facilitates digestion and decreases the risk for aspiration. Any obstruction requires that the feeding be stopped and the physician notified.

FIGURE 36-9 Protection at the gastrostomy site. A PEG tube may be protected by a dressing that allows access to the tube but covers the exit site. Typically the tube is stabilized with tape over the dressing. From Craven, R., & Hirnle, C. (2002). Fundamentals of nursing: Human health and function (4th ed.). Philadelphia: Lippincott Williams & Wilkins.
The patient or caregiver is instructed to flush the tube with 30 mL of water after each bolus or medication administration, and otherwise to flush the tube daily to keep it patent. Adaptors are available that can be secured to the end of the tube to create a “Y” site for ease of flushing or medication delivery. The flushing equipment is cleaned with warm, soapy water and rinsed after each use.

The patient and caregiver are made aware that the tube is marked at skin level to provide the patient a baseline for later comparison. They are advised to monitor the tube’s length and to notify the physician or home care nurse if the segment of the tube outside the body becomes shorter or longer.

If the patient is to use an intermittent or continuous-pressure feeding pump at home, instruction in the use of the particular type of pump is essential. Most feeding pumps have built-in alarms that signal when the bag is empty, when the battery is low, or when an occlusion is present. The patient and caregiver need to be aware of these alarms and how to troubleshoot the pump.

### Continuing Care

Referral to a home care agency is important to ensure initial supervision and support for the patient and caregiver. The home care nurse assesses the patient’s status and progress and evaluates the techniques that are used in administering the tube feeding. Further instruction and supervision in the home setting may be required to help the patient and caregiver adapt to a physical environment and equipment that are different from the hospital setting. The nurse also reviews with the patient and caregiver information about complications and any symptoms that occur. The nurse reviews the diary during home visits. When the tube is to be replaced, the patient or caregiver must be taught how to do this.

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Achieves an adequate intake of nutrients
   a. Tolerates quantity and frequency of tube feedings
   b. Has 50 mL or less of residual gastric content before each feeding
   c. Has no diarrhea
   d. Maintains or gains weight
   e. Has normal electrolyte values
2. Is free from infection and skin breakdown
   a. Is afebrile
   b. Has no drainage from the incision
   c. Demonstrates intact skin surrounding the exit site
   d. Inspects exit site twice a day
3. Adjusts to change in body image
   a. Is able to discuss expected changes
   b. Verbalizes concerns
   c. Asks to speak with someone who has experienced this procedure
4. Demonstrates skill in managing feeding regimen
   a. Helps prepare prescribed formula or blenderized food
   b. Handles equipment competently
   c. Helps administer the feeding or does so independently
   d. Demonstrates how to maintain tube patency
   e. Cleans tubing as needed
   f. Keeps an accurate record of intake
   g. Can remove and reinsert the tube as appropriate and needed for feedings
5. Avoids complications
   a. Exhibits adequate wound healing
   b. Has no abnormal bleeding from puncture site
   c. Tube remains intact for the duration of therapy

### Parenteral Nutrition

Parenteral nutrition (PN) is a method of providing nutrients to the body by an IV route. It is a very complex admixture of individual chemicals combined in a single container. The components of a PN admixture are proteins, carbohydrates, fats, electrolytes, vitamins, trace minerals, and sterile water. The goals of PN are to improve nutritional status, establish a positive nitrogen balance, maintain muscle mass, promote weight gain, and enhance the healing process.

### ESTABLISHING POSITIVE NITROGEN BALANCE

When a patient’s intake of protein and nutrients is significantly less than that required by the body to meet energy expenditures, a state of negative nitrogen balance results. In response, the body begins to convert the protein found in muscles into carbohydrates to be used to meet energy needs. The result is muscle wasting, weight loss, fatigue, and, if left uncorrected, death.

The average postoperative adult patient requires approximately 1500 calories per day to keep the body from using its own store of

---

**FIGURE 36-10** Bolus gastrostomy feeding by gravity. (A) Feeding is instilled at an angle so that air does not enter the stomach. (B) Syringe is raised perpendicular to the abdomen so that feeding can enter by gravity.
protein. Traditional IV fluids do not provide sufficient calories or nitrogen to meet the body’s daily requirements. PN solutions, which supply nutrients such as dextrose, amino acids, electrolytes, vitamins, minerals, and fat emulsions, provide enough calories and nitrogen to meet the patient’s daily nutritional needs. In general, PN can provide 30 to 35 kcal/kg of body weight and 1.0 to 1.5 g of protein/kg of body weight (Rombeau & Rolandelli, 2000).

The patient with fever, trauma, burns, major surgery, or hypermetabolic disease may require up to 10,000 additional calories daily. The volume of fluid necessary to provide these calories would surpass fluid tolerance and lead to pulmonary edema or heart failure. To provide the required calories in small volume, it is necessary to increase the concentration of nutrients and use a route of administration (ie, a large, high-flow vein [subclavian vein]) that will rapidly dilute incoming nutrients to the proper levels of body tolerance.

When highly concentrated glucose is administered, caloric requirements are satisfied and the body uses amino acids for protein synthesis rather than for energy. Additional potassium is added to the solution to maintain proper electrolyte balance and to transport glucose and amino acids across cell membranes. To prevent deficiencies and fulfill requirements for tissue synthesis, other elements, such as calcium, phosphorus, magnesium, and sodium chloride, are added (Rombeau & Rolandelli, 2000).

**CLINICAL INDICATIONS**

The indications for PN include a 10% deficit in body weight (compared with preillness weight), an inability to take oral food or fluids within 7 days after surgery, and hypermetabolic situations such as major infection with fever. In both the home and hospital setting, PN is indicated in the following situations:

- The patient’s intake is insufficient to maintain an anabolic state (eg, severe burns, malnutrition, short bowel syndrome, AIDS, sepsis, cancer).
- The patient’s ability to ingest food orally or by tube is impaired (eg, paralytic ileus, Crohn’s disease with obstruction, postradiation enteritis, severe hyperemesis gravidarum in pregnancy).
- The patient is not interested in or is unwilling to ingest adequate nutrients (eg, anorexia nervosa, postoperative elderly patients).
- The underlying medical condition precludes being fed orally or by tube (eg, acute pancreatitis, high enterocutaneous fistula).
- Preoperative and postoperative nutritional needs are prolonged (eg, extensive bowel surgery).

**FORMULAS**

A total of 2 to 3 L of solution is administered over a 24-hour period using a filter (1.2-micron particulate filter). Before administration, the PN infusion must be inspected for clarity and any precipitate. The label is compared with the physician’s order, noting the expiration date. Fat emulsions (Intralipid) may be infused simultaneously with PN through a Y-connector close to the infusion site. Fat emulsions should not be filtered. Before administration, the fat emulsion solution is inspected for frothiness, separation, or oily appearance. Usually 500 mL of a 10% emulsion is administered over 4 to 6 hours, one to three times a week. Fat emulsions can provide up to 30% of the total daily calorie intake.

Lipid emulsions can be admixed with other components of PN to create a total nutrient admixture (TNA). TNA is commonly called a “three-in-one” formulation. All the parenteral nutrient components are mixed in one container and administered to the patient over a 24-hour period. A special final filter (1.5 micron filter) is used with this solution. Before administration, the solution is observed for oil droplets that have separated from the solution, forming a noticeable layer (cracking of lipid emulsion); such a solution should be discarded. Advantages of the TNA over PN are cost savings in preparation and equipment, decreased risk of contamination, decreased risk of catheter contamination, decreased pharmacy preparation time, less nursing time, and increased patient convenience and satisfaction. Ideally, the pharmacist, nutritionist, and physician collaborate to determine the specific formula needed.

**INITIATING THERAPY**

PN solutions are initiated slowly and advanced gradually each day to the desired rate, as the patient’s fluid and glucose tolerance permits. The patient’s laboratory test results and response to PN therapy are monitored on an ongoing basis by the nutritional support team. Standing orders are initiated for weighing the patient; monitoring intake, output, and blood glucose; and baseline and periodic monitoring of complete blood count, platelet count, and chemistry panel, including serum carbon dioxide, magnesium, phosphorus, triglycerides, and prealbumin. A 24-hour urine nitrogen determination may be performed for analysis of nitrogen balance. In most hospitals, the physician prescribes PN solutions on a daily standard PN order form. The formulation of the PN solutions is calculated carefully each day to meet the complete nutritional needs of the individual patient.

**ADMINISTRATION METHODS**

Various vascular access devices are used to administer PN solutions in clinical practice. PN may be administered by either peripheral or central IV lines, depending on the patient’s condition and the anticipated length of therapy.

**Peripheral Method**

To supplement oral intake when complete bowel rest is not indicated and NG or nasoenteric suction is not required, a peripheral parenteral nutrition (PPN) formula may be prescribed. PPN is administered through a peripheral vein; this is possible because the solution is less hypertonic than PN solution. PPN formulas are not nutritionally complete. Protein and dextrose are limited. Dextrose concentrations of more than 10% should not be administered through peripheral veins because they irritate the intima (innermost walls) of small veins, causing chemical phlebitis. Lipids are administered simultaneously to buffer the PPN and to protect the peripheral vein from irritation. The usual length of therapy using PPN is 5 to 7 days (Hamilton, 2000).

**Central Method**

Because PN solutions have five or six times the solute concentration of blood (and exert an osmotic pressure of about 2000 mOsm/L), they are injurious to the intima of peripheral veins. Therefore, to prevent phlebitis and other venous complications, these solutions are administered into the vascular system through a catheter inserted into a high-flow, large blood vessel (the
subclavian vein). Concentrated solutions are then very rapidly diluted to isotonic levels by the blood in this vessel.

Four types of central venous access devices (CVAD) are available—nontunneled (or percutaneous) central catheters, peripherally inserted central catheters, tunneled catheters, and implanted ports. Whenever one of these catheters is inserted, catheter tip placement should be confirmed by x-ray studies before PN therapy is initiated. The optimal position is the midproximal third of the superior vena cava.

**NONTUNNELED CENTRAL CATHETERS**

Nontunneled central catheters are used for short-term (less than 30 days) IV therapy in the acute care, long-term care, and home care settings. The physician inserts these catheters. Examples of nontunneled central catheters are Vas Cath, Percutaneous Subclavian, and Hohn catheters. The subclavian vein is the most common vessel used, because the subclavian area provides a stable insertion site to which the catheter can be anchored, allows the patient freedom of movement, and provides easy access to the dressing site. The jugular or femoral vein also may be used. Single-, double-, and triple-lumen central catheters are available for central lines. To ensure accessibility, a triple-lumen subclavian catheter should be used, because it offers three ports for various uses (Fig. 36-11). The 16-gauge distal lumen can be used to infuse blood or other viscous fluids. The 18-gauge middle lumen is reserved for PN infusion. The 18-gauge proximal port can be used for administration of blood or medications. A port not being used for fluid administration can be used for obtaining blood specimens if indicated.

If a single-lumen central catheter is used for administering PN, various restrictions apply. Blood cannot be drawn from the catheter and medications cannot be administered through it, because the medication may be incompatible with the components of the nutritional solution (insulin is an exception). If medications must be given, they must be infused through a separate peripheral IV line, not by piggyback into the PN line. Transfusions of blood products also cannot be given through the main line, because red cells may possibly coat the lumen of the catheter, thereby reducing the flow of the nutritional solution.

**PERIPHERALLY INSERTED CENTRAL CATHETERS**

Peripherally inserted central catheters (PICC) are used for intermediate-term (3 to 12 months) IV therapy in the hospital, long-term care, or home setting. These catheters may be inserted at the bedside or in the outpatient setting by a specially trained nurse. The basilic or cephalic vein is accessed through the antecubital space, and the catheter is threaded to a designated location, depending on the type of solution to be infused (superior vena cava for PN). Taking of blood pressure and blood specimens from the extremity with the PICC is avoided (see Chapter 14).

**TUNNELED CENTRAL CATHETERS**

Tunneled central catheters are for long-term use and may remain in place for many years. These catheters are cuffed and can have single or double lumens; examples are the Hickman, Groshong, and Permacath. These catheters are inserted surgically. They are threaded under the skin (reducing the risk of ascending infection) to the subclavian vein, and the distal end of the catheter is advanced into the superior vena cava 2 to 3 cm above the junction with the right atrium (see Chapter 16).

**IMPLANTED PORTS**

Implanted ports are also used for long-term home IV therapy; examples include the Port-A-Cath, Mediport, Hickman Port, and P.A.S. Port. Instead of exiting from the skin, as do the Hickman and Groshong catheters, the end of the catheter is attached to a small chamber that is placed in a subcutaneous pocket, either on the anterior chest wall or on the forearm. The subcutaneous port requires minimal care and allows the patient complete freedom.
of activity. Implanted ports are more expensive than the external catheters, and access requires passing a special needle (Huber-tipped) through the skin into the chamber to initiate IV therapy (see Chapter 16). Taking of blood pressure and blood specimens from the extremity with the port system is avoided.

**NONTUNNELED CENTRAL CATHETER INSERTION**

The procedure is explained so that the patient understands the importance of not touching the catheter insertion site and is aware of what to expect during the insertion procedure. To insert the catheter, the patient is placed supine, in head-low position (to produce dilation of neck and shoulder vessels, which makes entry easier and prevents air embolus). The area is shaved if necessary, and the skin is prepared with acetone and alcohol to remove surface oils. Final skin preparation includes cleaning with tincture of 2% iodine or chlorhexidine. To afford maximal accuracy in the placement of the catheter, the patient is instructed to turn the head away from the site of venipuncture and to remain motionless while the catheter is inserted and the wound is dressed.

The preferred insertion route is the subclavian vein, which leads into the superior vena cava. The external jugular route can be used, but usually only in emergency situations. Because a non-tunneled central catheter is always a potential source of serious infection, the site should be changed every 4 weeks or as recommended by the Centers for Disease Control and Prevention.

Sterile drapes are applied to the upper chest. The patient may be asked to wear a facemask to prevent the spread of microorganisms. Procaine or lidocaine is injected to anesthetize the skin and underlying tissues. The target area is the inferior border at the midpoint of the clavicle. A large-bore needle on a syringe is inserted and moved parallel to and beneath the clavicle until it enters the vein. The syringe is then detached and a radiopaque catheter is inserted through the needle into the vein.

When the catheter is positioned, the needle is withdrawn and the hub of the catheter is attached to the IV tubing. Until the syringe is detached from the needle and the catheter is inserted, the patient may be asked to perform the Valsalva maneuver. (To do this, the patient is instructed to take a deep breath, hold it, and bear down with mouth closed. Compression of the abdomen may also accomplish the maneuver.) The Valsalva maneuver is performed to produce a positive phase in central venous pressure, to lessen the possibility of air being drawn into the circulatory system (air embolism). The physician suture the catheter to the skin to avoid inadvertent removal.

The catheter insertion site is swabbed with either tincture of 2% iodine or a chlorhexidine solution. A gauze or transparent dressing is applied using strict sterile technique. An isotonic IV solution, such as dextrose 5% in water (D5W), is administered to keep the vein patent.

The position of the tip of the catheter is checked with fluoroscopy to confirm its location in the superior vena cava and to rule out a pneumothorax resulting from puncture of the pleura. Once the catheter position is confirmed, the prescribed PN solution is started. The initial rate of infusion is usually 50 mL/hour, and the rate is gradually increased to the maintenance rate or predetermined dose (eg, 100 to 125 mL/hour). An infusion pump is always used for administration of PN or PPN.

An injection site cap is attached to the end of each central catheter lumen, creating a closed system. IV infusion tubing is connected to the insertion site cap of the central catheter with a threaded needleless adapter or Luer-lock device. Each lumen is labeled according to location (proximal, middle, distal). To ensure patency, all lumens are flushed with a diluted heparin flush initially, daily when not in use, after each intermittent infusion, after blood drawing, and whenever an infusion is disconnected. Force is never used to flush the catheter. If resistance is met, aspiration may be effective in cleansing the lumen; if this is not effective, the physician is notified. Low-dose t-PA (alteplase) may be prescribed to dissolve a clot or fibrin sheath. If attempts to clear the lumen are ineffective, the lumen is labeled as “clotted off.”

**DISCONTINUING PARENTERAL NUTRITION**

The PN solution is discontinued gradually to allow the patient to adjust to decreased levels of glucose. After administration of the PN solution is terminated, isotonic glucose is administered for several hours to prevent rebound hypoglycemia. Providing oral carbohydrates will shorten the tapering time. Specific symptoms of rebound hypoglycemia include weakness, faintness, sweating, shakiness, feeling cold, confusion, and increased heart rate. Once all IV therapy is completed, the nurse (with a physician’s order) removes the nontunneled central venous catheter or PICC and applies an occlusive dressing to the exit site. Tunneled catheters and implanted ports are removed by the physician.

In cases of serious illness when death is imminent, some patients or families may request that PN be discontinued. This difficult issue poses many ethical questions, some of which are discussed in Chart 36-3.

**NURSING PROCESS:**

**THE PATIENT RECEIVING PARENTERAL NUTRITION**

**Assessment**

The nurse assists in identifying patients who may be candidates for PN. Indicators include any significant weight loss (10% or more of usual weight), a decrease in oral food intake for more than 1 week, any significant sign of protein loss (serum albumin levels less than 3.2 g/dL [32 g/L], muscle wasting, decreased tissue healing, or abnormal urea nitrogen excretion), and persistent vomiting and diarrhea. The nurse carefully monitors the patient’s hydration, electrolyte levels, and calorie intake.

**Diagnosis**

**NURSING DIAGNOSES**

Based on the assessment data, the major nursing diagnoses may include the following:

- Imbalanced nutrition, less than body requirements, related to inadequate oral intake of nutrients
- Risk for infection related to contamination of the central catheter site or infusion line
- Risk for excess or deficient fluid volume related to altered infusion rate
- Risk for immobility related to fear that the catheter will become dislodged or occluded
- Risk for ineffective therapeutic regimen management related to knowledge deficit about home PN therapy

**COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS**

The most common complications are pneumothorax, air embolism, a clotted or displaced catheter, sepsis, hyperglycemia, rebound hypoglycemia, and fluid overload. These problems
and the associated collaborative interventions are described in Table 36-5.

**Planning and Goals**

The major goals for the patient may include optimal level of nutrition, absence of infection, adequate fluid volume, optimal level of activity (within individual limitations), knowledge of and skill in self-care, and prevention of complications.

**Nursing Interventions**

**MAINTAINING OPTIMAL NUTRITION**

A continuous, uniform infusion of PN solution over a 24-hour period is desired. In some cases, however (eg, home care patients), cyclic PN may be appropriate. With cyclic PN, there is a set time during a 24-hour period when PN is infused and a set time when it is not. The time periods for infusion are sufficient to meet the patient’s nutritional and pharmacologic needs. Ideally, cyclic PN is infused over an 8- to 10-hour period during the night.

The patient is weighed daily (this may be decreased to two or three times per week), at the same time of the day under the same conditions for accurate comparison. Under the PN regimen (without additional energy expenditure), a satisfactory weight gain is usually achieved. It is important to keep accurate intake and output records and calculations of fluid balance. A calorie count is kept of any oral nutrients. Trace elements (copper, zinc, chromium, manganese, and selenium) are included in PN solutions and are individualized for each patient. The PN solutions are prescribed daily by the physician on a standard PN order form based on laboratory values and patient tolerance.

**PREVENTING INFECTION**

The high glucose content of PN solutions makes these solutions ideal culture media for bacterial and fungal growth, and CVADs provide a port of entry. *Candida albicans* is the most common infectious organism. Other infectious organisms include *Staphylococcus aureus*, *Staphylococcus epidermidis*, and *Klebsiella pneumoniae*. Meticulous technique is essential to prevent infection.

The primary sources of microorganisms for catheter-related infections are the skin and the catheter hub. The catheter site is covered with an occlusive gauze dressing that is usually changed every other day. Alternatively, a transparent dressing may be used and changed weekly. The Centers for Disease Control and Prevention recommends changing dressings for CVADs only if they are damp, bloody, loose, or soiled. The dressings are changed using sterile technique. The nurse and patient wear masks during dressing changes to reduce the possibility of airborne contamination. The area is checked for leakage, bloody drainage, a kinked catheter, and skin reactions such as inflammation, redness, swelling, tenderness, or purulent drainage. The nurse puts on sterile gloves and cleanses the area with tincture of 2% iodine or a chlorhexidine solution on a sterile gauze. The site is cleaned thoroughly using circular motion from the site outward approximately 3 inches. This is repeated two times. This is followed with the same cleaning procedure using 2 × 2-inch gauze pads moistened with sterile water or saline solution (alcohol is used to remove iodine). Next the catheter lumens are cleaned from the exit site to the distal end with an alcohol wipe. The insertion site is covered with an occlusive gauze pad or transparent dressing centered over the area.

The advantages of using a transparent dressing over the gauze pad are that it allows frequent examination of the catheter site without changing the dressing, it adheres well, and it is more comfortable for the patient. When an extension set is used with a central catheter, it is considered an extension of the catheter itself. It is not routinely changed with dressing or tubing changes. The connection (hub) between the catheter and extension tubing is secured with adhesive tape to prevent separation and exposure to air. Main-line IV tubing and filters are changed every 72 to 96 hours, and all connections are taped securely to avoid breaks in the integrity of the system. The dressing and tubing are labeled with the date, time of insertion, time of dressing change, and initials of the person who carried out the procedure; this information is also documented in the medical record.

The catheter is another major source of colonization and infection. Antiseptic-impregnated central venous catheters are new devices that reduce catheter colonization by coating of the catheter surfaces with antimicrobial agents. Two types are available, one coated with chlorhexidine/silver sulfadiazine and the other with minocycline/rifampin (Hanna et al., 2001).

**MAINTAINING FLUID BALANCE**

An infusion pump is necessary for PN to maintain an accurate rate of administration. A designated rate is set in milliliters per hour, and the rate checked every 30 to 60 minutes. An alarm signals a problem. The infusion rate should not be increased or decreased...
to compensate for fluids that have infused too quickly or too slowly. If the solution runs out, 10% dextrose and water is infused until the next PN solution is available from the pharmacy.

If the rate is too rapid, hyperosmolar diuresis occurs (excess sugar will be excreted), which, if severe enough, can cause intractable seizures, coma, and death. Symptoms of rapid hypertonic fluid intake include headache, nausea, fever, chills, and increasing lethargy.

If the flow rate is too slow, the patient does not get the maximal benefit of calories and nitrogen. Intake and output are recorded every 8 hours so that fluid imbalance can be readily detected. The patient is weighed two or three times a week; in ideal situations, the patient will show neither weight loss nor significant weight gain. The nurse assesses for signs of dehydration (eg, thirst, decreased skin turgor, decreased central venous pressure) and reports these findings to the physician immediately. It is essential to monitor blood glucose levels, because hyperglycemia can cause diuresis and excessive fluid loss.

**Encouraging Activity**
Activities and ambulation are encouraged when the patient is physically capable. With a catheter in the subclavian vein, the patient is free to move the extremities and should be encouraged to maintain good muscle tone. If applicable, the teaching and exercise program initiated in the occupational and physical therapy departments should be reinforced.

**Promoting Home and Community-Based Care**

**Teaching Patients Self-Care**

Successful home PN requires teaching the patient and family specialized skills using an intensive training program and follow-up

</tbody>
</table>
An effective home care teaching program prepares the patient to manage the appropriate form of PN: how to store solutions, set up the infusion, flush the line with heparin, change the dressings, and troubleshoot for problems. The most common complication is sepsis. Strict aseptic technique is taught for hand hygiene, handling equipment, changing the dressing, and preparing the solution.

**Troubleshooting Mechanical Difficulties**
Mechanical problems usually arise from technical complications in the infusion pump or catheter site. The patient needs to know how to measure the length of the external portion of the catheter; this measurement is used as a comparison if the line is pulled or if dislodgement is suspected. The patient also needs to know how to recognize catheter problems (e.g., leakage, loose cap, blood clot, dislodgement) and should receive a list of instructions explaining what to do for each problem.

**Recognizing Metabolic Complications**
The patient is given a list of symptoms that indicate metabolic complications (neuropathies, mentation changes, diarrhea, nausea, skin changes, decreased urine output) and directions on how to contact the home health care nurse or physician if any of these complications occurs. The patient is instructed to have weekly serum chemistry and hematology tests as well.

**Obtaining Psychosocial Support**
The psychosocial aspects of home PN are as important as the physiologic and technical concerns. Patients must cope with the loss of eating and with changes in lifestyle brought on by sleep disturbances (frequent urination during infusions, usually two or three times during the night).

Major psychosocial reactions include depression, anger, withdrawal, anxiety, and impaired self-image. A successful home parenteral nutrition program depends on the patient’s and family’s motivation, emotional stability, and technical competence. Patients and families need to know which support groups are available in the community to help them cope with the transition and to minimize disruption of lifestyle.

**Continuing Care**
The home care nurse should be aware that the average patient needs about 2 weeks of instruction and reinforcement. For more information about home patient education, see Charts 36-4 and 36-5.

**Evaluation**
**EXPECTED PATIENT OUTCOMES**
Expected patient outcomes may include the following:

1. Attains or maintains nutritional balance
2. Is free of infection at the catheter site
   a. Is afebrile
   b. Has no purulent drainage from the catheter insertion site
   c. Has intact IV line
3. Is hydrated, as evidenced by good skin turgor
4. Achieves an optimal level of activity, within limitations
5. Demonstrates skill in managing PN regimen

---

**Chart 36-4 • PATIENT EDUCATION**
**Teaching Patients About Home Parenteral Nutrition**

At the completion of the home care instruction, the patient or caregiver will be able to:

- Discuss goal and purpose of PN therapy
- Discuss basic components of PN solution.
- List emergency phone numbers.
- Demonstrate how to handle PN solutions and medications correctly.
- Demonstrate how to operate infusion pump.
- Demonstrate how to prime tubing and filter.
- Demonstrate how to connect and disconnect PN infusion.
- Demonstrate how to perform catheter dressing changes.
- Demonstrate how to heparinize central line.
- Identify possible PN complications and interventions.

supervision in the home. This is accomplished through a team effort. The financial costs of such programs, although high, are less than those incurred in a hospital. Initiation of a home program may be the only way the patient can be discharged from the hospital.

Ideal candidates for home PN are those patients who have a reasonable life expectancy after return home, have only a limited number of medical illnesses other than the one that has resulted in the need for PN, and are highly motivated and fairly self-sufficient. In addition, ability to learn, availability of family interest and support, adequate finances, and the physical plan of the home are factors that must be assessed when the decision for home PN is made.

Home health care agencies sponsoring home PN programs have developed teaching brochures for every aspect of the treatment, including catheter and dressing care, use of an infusion pump, administration of fat emulsions, and instillation of heparin flushes. Teaching begins in the hospital and continues in the home or in an ambulatory infusion center.
6. Prevents complications
   a. Maintains proper catheter and equipment function
   b. Has no symptoms of sepsis
   c. Maintains metabolic balance within normal limits
   d. Shows improved and stabilized nutritional status

**Critical Thinking Exercises**

1. You are caring for a patient with an NG feeding tube. Before administering the patient’s tube feeding, you explain to the patient that you will be placing the tube to determine whether the patient is a candidate for home PN therapy. What assessment would you conduct to determine whether the patient is a candidate for home PN therapy?

2. A patient who is receiving gastrostomy tube feedings is to be discharged from the hospital to return home within the next few days. Several family members are to be taught how to administer the tube feedings. What are the learning priorities that should be accomplished before the patient is discharged? What assessment parameters should be used to determine whether the family has the necessary resources for providing care for the patient at home?

3. A patient who had major abdominal surgery 1 week ago and who has developed a paralytic ileus is to begin receiving PN. What explanation would you give to this patient about the benefits of PN and the procedure for its administration? PN. What is the rationale for providing care for this patient at home?

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Compare the etiology, clinical manifestations, and management of acute gastritis, chronic gastritis, and peptic ulcer.
2. Use the nursing process as a framework for care of patients with gastritis.
3. Use the nursing process as a framework for care of patients with peptic ulcer.
4. Describe the dietary, pharmacologic, and surgical treatment of peptic ulcer.
5. Describe the nursing management of patients who undergo surgical procedures to treat obesity.
6. Use the nursing process as a framework for care of patients with gastric cancer.
7. Use the nursing process as a framework for care of patients undergoing gastric surgery.
8. Identify the complications of gastric surgery and their prevention and management.
9. Describe the home health care needs of the patient who has had gastric surgery.
An individual’s nutritional status depends not only on the type and amount of intake but also on the functioning of the gastric and intestinal portions of the gastrointestinal (GI) system. This chapter describes disorders of the stomach and duodenum and their treatment.

Gastritis

Gastritis (inflammation of the gastric or stomach mucosa) is a common GI problem. Gastritis may be acute, lasting several hours to a few days, or chronic, resulting from repeated exposure to irritating agents or recurring episodes of acute gastritis.

Acute gastritis is often caused by dietary indiscretion—the person eats food that is contaminated with disease-causing microorganisms or that is irritating or too highly seasoned. Other causes of acute gastritis include overuse of aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs), excessive alcohol intake, bile reflux, and radiation therapy. A more severe form of acute gastritis is caused by the ingestion of strong acid or alkali, which may cause the mucosa to become gangrenous or to perforate. Scarring can occur, resulting in pyloric obstruction. Gastritis also may be the first sign of an acute systemic infection.

Chronic gastritis and prolonged inflammation of the stomach may be caused by either benign or malignant ulcers of the stomach or by the bacteria Helicobacter pylori. Chronic gastritis is sometimes associated with autoimmune diseases such as pernicious anemia; dietary factors such as caffeine; the use of medications, especially NSAIDs; alcohol; smoking; or reflux of intestinal contents into the stomach.

Pathophysiology

In gastritis, the gastric mucous membrane becomes edematous and hyperemic (congested with fluid and blood) and undergoes superficial erosion (Fig. 37-1). It secretes a scanty amount of gastric juice, containing very little acid but much mucus. Superficial ulceration may occur and can lead to hemorrhage.

Clinical Manifestations

The patient with acute gastritis may have abdominal discomfort, headache, lasitude, nausea, anorexia, vomiting, and hiccupping. Some patients, however, have no symptoms. The patient with chronic gastritis may complain of anorexia, heartburn after eating, belching, a sour taste in the mouth, or nausea and vomiting. Patients with chronic gastritis from vitamin deficiency usually have evidence of malabsorption of vitamin B12 caused by antibodies against intrinsic factor.

Assessment and Diagnostic Findings

Gastritis is sometimes associated with achlorhydria or hypochlorhydria (absence or low levels of hydrochloric acid [HCl]) or with hyperchlorhydria (high levels of HCl). Diagnosis can be determined by endoscopy, upper GI radiographic studies, and histologic examination of a tissue specimen obtained by biopsy. In addition to biopsy, other diagnostic measures for detecting H. pylori include serologic testing for antibodies against the H. pylori antigen, a 1-minute ultrarapid urease test, and a breath test.

Medical Management

The gastric mucosa is capable of repairing itself after a bout of gastritis. As a rule, the patient recovers in about 1 day, although the appetite may be diminished for an additional 2 or 3 days. Acute gastritis is also managed by instructing the patient to refrain from alcohol and food until symptoms subside. After the patient can take nourishment by mouth, a nonirritating diet is recommended. If the symptoms persist, fluids may need to be administered parenterally. If bleeding is present, management is similar to the procedures used for upper GI tract hemorrhage (discussed later in this chapter).

If gastritis is caused by ingestion of strong acids or alkalis, treatment consists of diluting and neutralizing the offending agent. To neutralize acids, common antacids (eg, aluminum hydroxide) are used; to neutralize an alkali, diluted lemon juice or diluted vinegar is used. If corrosion is extensive or severe, emetics and lavage are avoided because of the danger of perforation and damage to the esophagus.

Therapy is supportive and may include nasogastric (NG) intubation, analgesic agents and sedatives, antacids, and intravenous (IV) fluids. Fiberoptic endoscopy may be necessary. In extreme cases, emergency surgery may be required to remove gangrenous or perforated tissue. Gastrojejunostomy or gastric resection may be necessary to treat pyloric obstruction, a narrowing of the pyloric orifice.

Chronic gastritis is managed by modifying the patient’s diet, promoting rest, reducing stress, and initiating pharmacotherapy. H. pylori may be treated with antibiotics (eg, tetracycline or amoxicillin, combined with clarithromycin) and a proton pump inhibitor (eg, lansoprazole [Prevacid]), and possibly bismuth salts (Pepato-Bismol) (Table 37-1). Research is being conducted to develop a vaccine against H. pylori (Alshali et al., 2001).

NURSING PROCESS: THE PATIENT WITH GASTRITIS

Assessment

When obtaining the history, the nurse asks about the patient’s presenting signs and symptoms. Does the patient have heartburn, indigestion, nausea, or vomiting? Do the symptoms occur
at any specific time of the day, before or after meals, after ingesting spicy or irritating foods, or after the ingestion of certain drugs or alcohol? Has there been recent weight gain or loss? Are the symptoms related to anxiety, stress, allergies, eating or drinking too much, or eating too quickly? How are the symptoms relieved? Is there a history of previous gastric disease or surgery? A diet history plus a 72-hour dietary recall (a list of everything the patient ate and drank in the last 72 hours) may be helpful.

A thorough history is important because it helps the nurse to identify whether known dietary excesses or other indiscretions are associated with the current symptoms, whether others in the patient’s environment have similar symptoms, whether the patient is vomiting blood, and whether any known caustic element has been ingested. The nurse also identifies the duration of the current symptoms, any methods used by the patient to treat these symptoms, and whether the methods are effective. Signs to note during the physical examination include abdominal tenderness, dehydration, and evidence of any systemic disorder that might be responsible for the symptoms of gastritis.

**Nursing Diagnoses**

Based on the assessment data, the patient’s major nursing diagnoses may include the following:

- Anxiety related to treatment
- Imbalanced nutrition, less than body requirements, related to inadequate intake of nutrients
- Risk for imbalanced fluid volume related to insufficient fluid intake and excessive fluid loss subsequent to vomiting
- Deficient knowledge about dietary management and disease process
- Acute pain related to irritated stomach mucosa

**Planning and Goals**

The major goals for the patient may include reduced anxiety, avoidance of irritating foods, adequate intake of nutrients, maintenance of fluid balance, increased awareness of dietary management, and relief of pain.

**Nursing Interventions**

**REDUCING ANXIETY**

If the patient has ingested acids or alkalis, emergency measures may be needed. The nurse offers supportive therapy to the patient and family during treatment and after the ingested acid or alkali has been neutralized or diluted. In some cases, the nurse may need to prepare the patient for additional diagnostic studies (endoscopy) or surgery. The patient usually feels anxious about the pain and the treatment modalities. The nurse uses a calm approach to assess the patient and to answer all questions as completely as possible. It is important to explain all procedures and treatments according to the patient’s level of understanding.

**PROMOTING OPTIMAL NUTRITION**

For acute gastritis, the nurse provides physical and emotional support and helps the patient manage the symptoms, which may include nausea, vomiting, heartburn, and fatigue. The patient should take no foods or fluids by mouth—possibly for days—until the acute symptoms subside, thus allowing the gastric mucosa to heal. If IV therapy is necessary, the nurse monitors it regularly, along with serum electrolyte values. After the symptoms subside, the nurse can offer the patient ice chips followed by clear liquids. Introducing solid food as soon as possible will provide oral nutrition, decrease the need for IV therapy, and minimize irritation to the gastric mucosa. As food is introduced, the nurse evaluates and reports any symptoms that suggest a repeat episode of gastritis.

<tr>
<td>Rabeprazole (Aciphex)</td>
<td>Decreases gastric acid secretion by slowing the H+, K+ -ATPase pump on the surface of the parietal cells</td>
<td>A delayed-release tablet; swallow whole.</td>
</tr>
</tbody>
</table>

(continued)
The nurse discourages the intake of caffeinated beverages, because caffeine is a central nervous system stimulant that increases gastric activity and pepsin secretion. It also is important to discourage alcohol use. Discouraging cigarette smoking is important because nicotine reduces the secretion of pancreatic bicarbonate and thus inhibits the neutralization of gastric acid in the duodenum (Eastwood, 1997). When appropriate, the nurse refers the patient for alcohol counseling and smoking cessation programs.

**PROMOTING FLUID BALANCE**

Daily fluid intake and output are monitored to detect early signs of dehydration (minimal urine output of 30 mL/hour, minimal intake of 1.5 L/day). If food and fluids are withheld, IV fluids (3 L/day) usually are prescribed and a record of fluid intake plus caloric value (1 L of 5% dextrose in water = 170 calories of carbohydrate) needs to be maintained. Electrolyte values (sodium, potassium, chloride) are assessed every 24 hours to detect imbalance.

The nurse must always be alert for any indicators of hemorrhagic gastritis, which include hematemesis (vomiting of blood), tachycardia, and hypotension. If these occur, the physician is notified and the patient’s vital signs are monitored as the patient’s condition warrants. Guidelines for managing upper GI tract bleeding are discussed later in this chapter.

**RELIEVING PAIN**

Measures to help relieve pain include instructing the patient to avoid foods and beverages that may be irritating to the gastric mucosa (described earlier) and instructing the patient about using medications to relieve chronic gastritis. To follow up, the nurse assesses the patient’s level of pain and the extent of comfort attained from the use of medications and avoidance of irritating substances.

**PROMOTING HOME AND COMMUNITY-BASED CARE**

**Teaching Patients Self-Care**

The nurse evaluates the patient’s knowledge about gastritis and develops an individualized teaching plan that includes information about stress management, diet, and medications (Chart 37-1). Dietary instructions take into account the patient’s daily caloric needs, food preferences, and pattern of eating. The nurse and patient review foods and other substances to be avoided (eg, spicy, irritating, or highly seasoned foods; caffeine; nicotine; alcohol). Consultation with a dietitian may be recommended.

Providing information about prescribed antibiotics, bismuth salts, medications to decrease gastric secretion, and medications to protect mucosal cells from gastric secretions can help the patient recover and prevent recurrence. Patients with pernicious anemia need information about long-term vitamin B₁₂ injections; the nurse may instruct a family member about administering these injections or make arrangements for the patient to receive the injections from a health care provider. Finally, the nurse emphasizes the importance of keeping follow-up appointments with health care providers.

**Evaluation**

**EXPECTED PATIENT OUTCOMES**

Expected patient outcomes may include the following:

1. Exhibits less anxiety
2. Avoids eating irritating foods or drinking caffeinated beverages or alcohol
3. Maintains fluid balance
   a. Has intake of at least 1.5 L daily
   b. Drinks six to eight glasses of water daily

**Chart 37-1 • Home Care Checklist • The Patient With Gastritis**

At the completion of the home care instruction, the patient or caregiver will be able to:

- Identify foods and other substances that may cause gastritis. 
  
  Patient: ✓  
  Caregiver: ✓

- Describe medication regimen to follow. 
  
  Patient: ✓  
  Caregiver: ✓

- State need for vitamin B₁₂ injections if patient has pernicious anemia. 
  
  Patient: ✓  
  Caregiver: ✓
c. Has a urinary output of about 1 L daily
d. Displays adequate skin turgor
4. Adheres to medical regimen
   a. Selects nonirritating foods and beverages
   b. Takes medications as prescribed
5. Maintains appropriate weight
6. Reports less pain

Gastric and Duodenal Ulcers

A peptic ulcer is an excavation (hollowed-out area) that forms in the mucosal wall of the stomach, in the pylorus (opening between stomach and duodenum), in the duodenum (first part of small intestine), or in the esophagus. A peptic ulcer is frequently referred to as a gastric, duodenal, or esophageal ulcer, depending on its location, or as peptic ulcer disease. Erosion of a circumscribed area of mucous membrane is the cause (Fig. 37-2). This erosion may extend as deeply as the muscle layers or through the muscle to the peritoneum. Peptic ulcers are more likely to be in the duodenum than in the stomach. As a rule they occur alone, but they may occur in multiples. Chronic gastric ulcers tend to occur in the lesser curvature of the stomach, near the pylorus.

Table 37-2 compares the features of gastric and duodenal ulcers.

</table>

In the past, stress and anxiety were thought to be causes of ulcers. Research has identified that peptic ulcers result from infection with the gram-negative bacteria *H. pylori* (Tytgat, 2000). However, ulcers do seem to develop more commonly in people who are tense; whether this is a contributing factor to the condition is uncertain. In addition, excessive secretion of HCl in the stomach may contribute to the formation of gastric ulcers, and stress may be associated with its increased secretion. The ingestion of milk and caffeinated beverages, smoking, and alcohol also may increase HCl secretion.

Familial tendency may be a significant predisposing factor. A further genetic link is noted in the finding that people with blood type O are more susceptible to peptic ulcers than are those with blood type A, B, or AB. There also is an association between duodenal ulcers and chronic pulmonary disease or chronic renal disease. Other predisposing factors associated with peptic ulcer include chronic use of NSAIDs, alcohol ingestion, and excessive smoking.

Rarely, ulcers are caused by excessive amounts of the hormone gastrin, produced by tumors. This Zollinger-Ellison syndrome (ZES) consists of severe peptic ulcers, extreme gastric hyperacidity, and gastrin-secreting benign or malignant tumors of the pancreas. Stress ulcers, which are clinically different from peptic ulcers, are ulceraations in the mucosa that can occur in the gastro-duodenal area. Stress ulcers may occur in patients who are exposed to stressful conditions. Esophageal ulcers occur as a result of the backward flow of HCl from the stomach into the esophagus (gastroesophageal reflux disease [GERD]).
Pathophysiology

Peptic ulcers occur mainly in the gastroduodenal mucosa because this tissue cannot withstand the digestive action of gastric acid (HCl) and pepsin. The erosion is caused by the increased concentration or activity of acid- pepsin, or by decreased resistance of the mucosa. A damaged mucosa cannot secrete enough mucus to act as a barrier against HCl. The use of NSAIDs inhibits the secretion of mucus that protects the mucosa. Patients with duodenal ulcer disease secrete more acid than normal, whereas patients with gastric ulcer tend to secrete normal or decreased levels of acid.

ZES is suspected when a patient has several peptic ulcers or an ulcer that is resistant to standard medical therapy. It is identified by the following findings: hypersecretion of gastric juice, duodenal ulcers, and gastrinomas (islet cell tumors) in the pancreas. Ninety percent of tumors are found in the “gastric triangle,” which encompasses the cystic and common bile ducts, the second and third portions of the duodenum, and the neck and body of the pancreas. Approximately one third of gastrinomas are malignant. Diarrhea and steatorrhea (unabsorbed fat in the stool) may be evident. The patient may have coexisting parathyroid adenomas or hyperplasia and may therefore exhibit signs of hypercalcemia. The most common complaint is epigastric pain. H. pylori is not a risk factor for ZES.

Stress ulcer is the term given to the acute mucosal ulceration of the duodenal or gastric area that occurs after physiologically stressful events, such as burns, shock, severe sepsis, and multiple organ traumas. These ulcers are most common in ventilator-dependent patients after trauma or surgery. Fiberoptic endoscopy within 24 hours after injury reveals shallow erosions of the stomach wall; by 72 hours, multiple gastric erosions are observed. As the stressful condition continues, the ulcers spread. When the patient recovers, the lesions are reversed. This pattern is typical of stress ulceration.

Differences of opinion exist as to the actual cause of mucosal ulceration in stress ulcers. Usually, it is preceded by shock; this leads to decreased gastric mucosal blood flow and to reflux of duodenal contents into the stomach. In addition, large quantities of pepsin are released. The combination of ischemia, acid, and pepsin creates an ideal climate for ulceration.

Stress ulcers should be distinguished from Cushing’s ulcers and Curling’s ulcers, two other types of gastric ulcers. Cushing’s ulcers are common in patients with trauma to the brain. They may occur in the esophagus, stomach, or duodenum and are usually deeper and more penetrating than stress ulcers. Curling’s ulcer is frequently observed about 72 hours after extensive burns and involves the antrum of the stomach or the duodenum.

Clinical Manifestations

Symptoms of an ulcer may last for a few days, weeks, or months and may disappear only to reappear, often without an identifiable cause. Many people have symptomless ulcers, and in 20% to 30% perforation or hemorrhage may occur without any preceding manifestations.

As a rule, the patient with an ulcer complains of dull, gnawing pain or a burning sensation in the midepigastrium or in the back. It is believed that the pain occurs when the increased acid content of the stomach and duodenum erodes the lesion and stimulates the exposed nerve endings. Another theory suggests that contact of the lesion with acid stimulates a local reflex mechanism that initiates contraction of the adjacent smooth muscle. Pain is usually relieved by eating, because food neutralizes the acid, or by taking alkali; however, once the stomach has emptied or the alkali’s effect has decreased, the pain returns. Sharply localized tenderness can be elicited by applying gentle pressure to the epigastrium or slightly to the right of the midline.

Other symptoms include pyrosis (heartburn), vomiting, constipation or diarrhea, and bleeding. Pyrosis is a burning sensation in the esophagus and stomach that moves up to the mouth. Heartburn is often accompanied by sour eructation, or burping, which is common when the patient’s stomach is empty.

Although vomiting is rare in uncomplicated duodenal ulcer, it may be a symptom of a peptic ulcer complication. It results from obstruction of the pyloric orifice, caused by either muscular spasm of the pylorus or mechanical obstruction from scarring or acute swelling of the inflamed mucous membrane adjacent to the ulcer. Vomiting may or may not be preceded by nausea; usually it follows a bout of severe pain and bloating, which is relieved by ejection of the gastric contents. Emesis often contains undigested food eaten many hours earlier. Constipation or diarrhea can occur, probably as a result of diet and medications.

Fifteen percent of patients with gastric ulcers experience bleeding. Patients may present with GI bleeding as evidenced by the passage of tarry stools. A small portion of patients who bleed from an acute ulcer have had no previous digestive complaints, but they develop symptoms thereafter (Yamada, 1999).

Assessment and Diagnostic Findings

A physical examination may reveal pain, epigastric tenderness, or abdominal distention. A barium study of the upper GI tract may show an ulcer; however, endoscopy is the preferred diagnostic procedure because it allows direct visualization of inflammatory changes, ulcers, and lesions. Through endoscopy, a biopsy of the gastric mucosa and of any suspicious lesions can be obtained. Endoscopy may reveal lesions that are not evident on x-ray studies because of their size or location.

Stools may be tested periodically until they are negative for occult blood. Gastric secretory studies are of value in diagnosing achlorhydria and ZES. H. pylori infection may be determined by biopsy and histology with culture. There is also a breath test that detects H. pylori, as well as a serologic test for antibodies to the H. pylori antigen. Pain that is relieved by ingesting food or antacids and absence of pain on arising are also highly suggestive of an ulcer.

Medical Management

Once the diagnosis is established, the patient is informed that the problem can be controlled. Recurrence may develop; however, peptic ulcers treated with antibiotics to eradicate H. pylori have a lower recurrence rate than those not treated with antibiotics. The goals are to eradicate H. pylori and to manage gastric acidity. Methods used include medications, lifestyle changes, and surgical intervention.

PHARMACOLOGIC THERAPY

Currently, the most commonly used therapy in the treatment of ulcers is a combination of antibiotics, proton pump inhibitors, and bismuth salts that suppresses or eradicates H. pylori; histrmine 2 (H2) receptor antagonists and proton pump inhibitors are used to treat NSAID-induced and other ulcers not associated with H. pylori ulcers. Table 37-1 provides details about pharmacologic treatment.
The patient is advised to adhere to the medication regimen to ensure complete healing of the ulcer. Because most patients become symptom-free within a week, it becomes a nursing responsibility to stress the importance of following the prescribed regimen so that the healing process can continue uninterrupted and the return of chronic ulcer symptoms can be prevented. Rest, sedatives, and tranquilizers may add to the patient’s comfort and are prescribed as needed. Maintenance dosages of H$_2$ receptor antagonists are usually recommended for 1 year.

For patients with ZES, hypersecretion of acid may be controlled with high doses of H$_2$ receptor antagonists. These patients may require twice the normal dose, and dosages usually need to be increased with prolonged use. Octreotide (Sandostatin), a medication that suppresses gastric levels, also may be prescribed.

Patients at risk for stress ulcers may be treated prophylactically with IV H$_2$ receptor antagonists and cytoprotective agents (e.g., misoprostol, sucralfate) because of the risk for upper GI tract hemorrhage. Frequent gastric aspiration is performed to allow monitoring of gastric secretion pH.

STRESS REDUCTION AND REST
Reducing environmental stress requires physical and psychological modifications on the patient’s part as well as the aid and cooperation of family members and significant others. The patient may need help in identifying situations that are stressful or exhausting. A rushed lifestyle and an irregular schedule may aggravate symptoms and interfere with regular meals taken in relaxed settings and with the regular administration of medications. The patient may benefit from regular rest periods during the day, at least during the acute phase of the disease. Biofeedback, hypnosis, or behavior modification may be helpful.

SMOKING CESSION
Studies have shown that smoking decreases the secretion of bicarbonate from the pancreas into the duodenum, resulting in increased acidity of the duodenum. Research indicates that continuing to smoke cigarettes may significantly inhibit ulcer repair. Therefore, the patient is strongly encouraged to stop smoking. Smoking cessation support groups and other smoking cessation approaches are helpful for many patients (Eastwood, 1997).

DIETARY MODIFICATION
The intent of dietary modification for patients with peptic ulcers is to avoid oversecretion of acid and hypermotility in the GI tract. These can be minimized by avoiding extremes of temperature and overstimulation from consumption of meat extracts, alcohol, coffee (including decaffeinated coffee, which also stimulates acid secretion) and other caffeinated beverages, and diets rich in milk and cream (which stimulate acid secretion). In addition, an effort is made to neutralize acid by eating three regular meals a day. Small, frequent feedings are not necessary as long as an antacid or a histamine blocker is taken. Diet compatibility becomes an individual matter: the patient eats foods that can be tolerated and of H$_2$ H. pylori and of H$_2$ receptor antagonists as treatment for ulcers has greatly reduced the need for surgical interventions. However, surgery is usually recommended for patients with intractable ulcers (those that fail to heal after 12 to 16 weeks of medical treatment), life-threatening hemorrhage, perforation, or obstruction, and for those with ZES not responding to medications (Yamada, 1999). Surgical procedures include vagotomy, with or without pyloroplasty, and the Billroth I and Billroth II procedures (Table 37-3; see also the section on gastric surgery later in this chapter). Patients who need ulcer surgery may have had a long illness. They may be discouraged and have had interruptions in their work role and pressures in their family life.

FOLLOW-UP CARE
Recurrence within 1 year may be prevented with the prophylactic use of H$_2$ receptor antagonists given at a reduced dose. Not all patients require maintenance therapy; it may be prescribed only for those with two or three recurrences per year, those who have had a complication such as bleeding or outlet obstruction, or those who are candidates for gastric surgery but are at too high a risk for surgery. The likelihood of recurrence is reduced if the patient avoids smoking, coffee (including decaffeinated coffee) and other caffeinated beverages, alcohol, and ulcerogenic medications (e.g., NSAIDs).

NURSING PROCESS: THE PATIENT WITH ULCER DISEASE
Assessment
The nurse asks the patient to describe the pain and the methods used to relieve it (e.g., food, antacids). The patient usually describes peptic ulcer pain as burning or gnawing; it occurs about 2 hours after a meal and frequently awakens the patient between midnight and 3 AM. Taking antacids, eating, or vomiting often relieves the pain. If the patient reports a recent history of vomiting, the nurse determines how often emesis has occurred and notes important characteristics of the vomitus: Is it bright red, does it resemble coffee grounds, or is there undigested food from previous meals? Has the patient noted any bloody or tarry stools?

The nurse also asks the patient to list his or her usual food intake for a 72-hour period and to describe food habits (e.g., speed of eating, regularity of meals, preference for spicy foods, use of seasonings, use of caffeinated beverages and decaffeinated coffee). Lifestyle and habits are a concern as well. Does the patient use irritating substances? For example, does he or she smoke cigarettes? If yes, how many? Does the patient ingest alcohol? If yes, how much and how often? Are NSAIDs used? The nurse inquires about the patient’s level of anxiety and his or her perception of current stressors. How does the patient express anger or cope with stressful situations? Is the patient experiencing occupational stress or problems within the family? Is there a family history of ulcer disease?

The nurse assesses vital signs and reports tachycardia and hypotension, which may indicate anemia from GI bleeding. The stool is tested for occult blood, and a physical examination, including palpation of the abdomen for localized tenderness, is performed as well.

Diagnosis
NURSING DIAGNOSES
Based on the assessment data, the patient’s nursing diagnoses may include the following:

- Acute pain related to the effect of gastric acid secretion on damaged tissue
- Anxiety related to coping with an acute disease
- Imbalanced nutrition related to changes in diet
- Deficient knowledge about prevention of symptoms and management of the condition
### Table 37-3 • Surgical Procedures for Peptic Ulcer Disease

<tr>
<td><strong>Vagotomy</strong></td>
<td>Severing of the vagus nerve. Decreases gastric acid by diminishing cholinergic stimulation to the parietal cells, making them less responsive to gastrin. May be done via open surgical approach, laparoscopy, or thoracoscopy</td>
<td>May be performed to reduce gastric acid secretion. A drainage type of procedure (see pyloroplasty) is usually performed to assist with gastric emptying (because there is total denervation of the stomach). Some patients experience problems with feeling of fullness, dumping syndrome, diarrhea, and gastritis.</td>
</tr>
<tr>
<td><strong>Truncal vagotomy</strong></td>
<td>Severs the right and left vagus nerves as they enter the stomach at the distal part of the esophagus.</td>
<td>This type of vagotomy is most commonly used to decrease acid secretions and reduce gastric and intestinal motility. Recurrence rate of ulcer is 10%–15%.</td>
</tr>
<tr>
<td><strong>Selective vagotomy</strong></td>
<td>Severs vagal innervation to the stomach but maintains innervation to the rest of the abdominal organs.</td>
<td>No dumping syndrome. No need for drainage procedure. Recurrence rate of ulcer is 10%–15%.</td>
</tr>
<tr>
<td><strong>Proximal (parietal cell) gastric vagotomy without drainage</strong></td>
<td>Denervates acid-secreting parietal cells but preserves vagal innervation to the gastric antrum and pylorus.</td>
<td>Usually accompanies truncal and selective vagotomies, which produce delayed gastric emptying due to decreased innervation.</td>
</tr>
<tr>
<td><strong>Pyloroplasty</strong></td>
<td>A surgical procedure in which a longitudinal incision is made into the pylorus and transversely sutured closed to enlarge the outlet and relax the muscle</td>
<td></td>
</tr>
<tr>
<td><strong>Antrectomy</strong></td>
<td>Removal of the lower portion of the antrum of the stomach (which contains the cells that secrete gastrin) as well as a small portion of the duodenum and pylorus. The remaining segment is anastomosed to the duodenum (Billroth I) or to the jejunum (Billroth II)</td>
<td>May be performed in conjunction with a truncal vagotomy. The patient may have problems with feeling of fullness, dumping syndrome, and diarrhea. Recurrence rate of ulcer is &lt; 1%.</td>
</tr>
</tbody>
</table>

(continued)
Potential complications may include the following:

- Hemorrhage
- Perforation
- Penetration
- Pyloric obstruction (gastric outlet obstruction)

Planning and Goals

The goals for the patient may include relief of pain, reduced anxiety, maintenance of nutritional requirements, knowledge about the management and prevention of ulcer recurrence, and absence of complications.

Nursing Interventions

RElieving Pain

Pain relief can be achieved with prescribed medications. The patient should avoid aspirin, foods and beverages that contain caffeine, and decaffeinated coffee, and meals should be eaten at regularly paced intervals in a relaxed setting. Some patients benefit from learning relaxation techniques to help manage stress and pain and to enhance smoking cessation efforts.

Reducing Anxiety

The nurse assesses the patient’s level of anxiety. Patients with peptic ulcers are usually anxious, but their anxiety is not always obvious. Appropriate information is provided at the patient’s level of understanding, all questions are answered, and the patient is encouraged to express fears openly. Explaining diagnostic tests and administering medications on schedule also help to reduce anxiety. The nurse interacts with the patient in a relaxed manner, helps identify stressors, and explains various coping techniques and relaxation methods, such as biofeedback, hypnosis, or behavior modification. The patient’s family is also encouraged to participate in care and to provide emotional support.

Maintaining Optimal Nutritional Status

The nurse assesses the patient for malnutrition and weight loss. After recovery from an acute phase of peptic ulcer disease, the patient is advised about the importance of complying with the medication regimen and dietary restrictions.

Monitoring and Managing Potential Complications

Hemorrhage

Gastritis and hemorrhage from peptic ulcer are the two most common causes of upper GI tract bleeding (which may also occur with esophageal varices, as discussed in Chapter 39). Hemorrhage, the most common complication, occurs in about 15% of patients with peptic ulcers (Yamada, 1999). The site of bleeding is usually the distal portion of the duodenum. Bleeding may be manifested by hematemesis or melena (tarry stools). The vomited blood can be bright red, or it can have a “coffee grounds” appearance (which is dark) from the oxidation of hemoglobin to methemoglobin. When the hemorrhage is large (2000 to 3000 mL), most of the blood is vomited. Because large quantities of blood may be lost quickly, immediate correction of blood loss may be required to prevent hemorrhagic shock. When the hemorrhage is small, much or all of the blood is passed in the stools, which will appear tarry black because of the digested hemoglobin. Management depends on the amount of blood lost and the rate of bleeding.

The nurse assesses the patient for faintness or dizziness and nausea, which may precede or accompany bleeding. It is important to monitor vital signs frequently and to evaluate the patient for tachycardia, hypotension, and tachypnea. Other nursing interventions include monitoring the hemoglobin and hematocrit,

<table>

**Table 37-3 • Surgical Procedures for Peptic Ulcer Disease**

(Continued)
testing the stool for gross or occult blood, and recording hourly urinary output to detect anuria or oliguria (absence or decreased urine production).

Many times the bleeding from a peptic ulcer stops spontaneously; however, the incidence of recurrent bleeding is high. Because bleeding can be fatal, the cause and severity of the hemorrhage must be identified quickly and the blood lost treated to prevent hemorrhagic shock. Management of upper GI tract bleeding consists of quickly determining the amount of blood lost and the rate of bleeding, rapidly replacing the blood that has been lost, stopping the bleeding, stabilizing the patient, and diagnosing and treating the cause. Related nursing and collaborative interventions include the following:

- Inserting a peripheral IV line for the infusion of saline or lactated Ringer’s solution and blood products. The nurse may need to assist with the placement of a pulmonary artery catheter for hemodynamic monitoring. Blood component therapy is initiated if there are signs of shock (eg, tachycardia, sweating, coldness of the extremities).
- Monitoring the hemoglobin and hematocrit to assist in evaluating blood loss
- Inserting an NG tube to distinguish fresh blood from “coffee grounds” material, to aid in the removal of clots and acid, to prevent nausea and vomiting, and to provide a means of monitoring further bleeding
- Administering a room-temperature lavage of saline solution or water. This is controversial; some authorities recommend using ice lavage (Yamada, 1999).
- Inserting an indwelling urinary catheter and monitoring urinary output
- Monitoring vital signs and oxygen saturation and administering oxygen therapy
- Placing the patient in the recumbent position with the legs elevated to prevent hypotension; or, to prevent aspiration from vomiting, placing the patient on the left side
- Treating hemorrhagic shock (described in Chapter 15)

If bleeding cannot be managed by the measures described, other treatment modalities may be used. Transendoscopic coagulation by laser, heat probe, medication, a sclerosing agent, or a combination of these therapies can halt bleeding and make surgical intervention unnecessary. There is much debate regarding how soon endoscopy should be performed. Some believe that endoscopy should be performed in the first 24 hours after hemorrhage has been stabilized. Others believe that endoscopy may be performed during acute bleeding, as long as the esophageal or gastric area can be visualized (blood may decrease visibility) (Yamada, 1999).

For those who are unable to undergo surgery, selective embolization may be used. This procedure involves forcing emboli of autologous blood clots with or without Gelfoam (absorbable gelatin sponge) through a catheter in the artery to a point above the bleeding lesion. A radiologist performs this procedure.

Rebleeding may occur and often warrants surgical intervention. The nurse monitors the patient carefully so that bleeding can be detected quickly. Signs of bleeding include tachycardia, tachypnea, hypotension, mental confusion, thirst, and oliguria. If bleeding recurs within 48 hours after medical therapy has begun, or if more than 6 to 10 units of blood are required within 24 hours to maintain blood volume, the patient is likely to require surgery. Some physicians recommend surgical intervention if a patient hemorrhages three times. Other criteria for surgery are the patient’s age (massive hemorrhaging is three times more likely to be fatal in those older than 60 years of age); a history of chronic duodenal ulcer; and a coincidental gastric ulcer (Yamada, 1999). The area of the ulcer is removed or the bleeding vessels are ligated. Many patients also undergo procedures (eg, vagotomy and pyloroplasty, gastrectomy) aimed at controlling the underlying cause of the ulcers (see Table 37-3).

**Perforation and Penetration**

Perforation is the erosion of the ulcer through the gastric serosa into the peritoneal cavity without warning. It is an abdominal catastrophe and requires immediate surgery. Penetration is erosion of the ulcer through the gastric serosa into adjacent structures such as the pancreas, biliary tract, or gastrohepatic omentum. Symptoms of penetration include back and epigastric pain not relieved by medications that were effective in the past. Like perforation, penetration usually requires surgical intervention.

Signs and symptoms of perforation include the following:

- Sudden, severe upper abdominal pain (persisting and increasing in intensity); pain may be referred to the shoulders, especially the right shoulder, because of irritation of the phrenic nerve in the diaphragm.
- Vomiting and collapse (fainting)
- Extremely tender and rigid (boardlike) abdomen
- Hypotension and tachycardia, indicating shock

Because chemical peritonitis develops within a few hours after perforation and is followed by bacterial peritonitis, the perforation must be closed as quickly as possible. In a few patients, it may be deemed safe and advisable to perform surgery for the ulcer disease in addition to suturing the perforation.

Postoperatively, the stomach contents are drained by means of an NG tube. The nurse monitors fluid and electrolyte balance and assesses the patient for peritonitis or localized infection (increased temperature, abdominal pain, paralytic ileus, increased or absent bowel sounds, abdominal distention). Antibiotic therapy is administered parenterally as prescribed.

**Pyloric Obstruction**

Pyloric obstruction, also called gastric outlet obstruction (GOO), occurs when the area distal to the pyloric sphincter becomes scarred and stenosed from spasm or edema or from scar tissue that forms when an ulcer alternately heals and breaks down. The patient has nausea and vomiting, constipation, epigastric fullness, anorexia, and, later, weight loss.

In treating the patient with pyloric obstruction, the first consideration is to insert an NG tube to decompress the stomach. Confirmation that obstruction is the cause of the discomfort is accomplished by assessing the amount of fluid aspirated from the NG tube. A residual of more than 400 mL strongly suggests obstruction. Usually an upper GI study or endoscopy is performed to confirm gastric outlet obstruction. Decompression of the stomach and management of extracellular fluid volume and electrolyte balances may improve the patient’s condition and avert the need for surgical intervention. A balloon dilatation of the pylorus via endoscopy may be beneficial. If the obstruction is unrelieved by medical management, surgery (in the form of a vagotomy and antrectomy or gastrojejunostomy and vagotomy) may be required.

**PROMOTING HOME AND COMMUNITY-BASED CARE**

**Teaching Patients Self-Care**

To manage ulcer disease successfully, the patient is instructed about the factors that will help or aggravate the condition (Chart 37-2). The nurse reviews information about medications to be taken at
home, including name, dosage, frequency, and possible side effects, stressing the importance of continuing to take medications even after signs and symptoms have decreased or subsided. Then the patient is instructed to avoid certain medications and foods that exacerbate symptoms as well as substances that have acid-producing potential (eg, alcohol; caffeinated beverages such as coffee, tea, and colas). It is important to counsel the patient to eat meals at regular times and in a relaxed setting, and to avoid overeating. If relevant, the nurse also informs the patient about the irritant effects of smoking on the ulcer and provides information about smoking cessation programs.

The nurse reinforces the importance of follow-up care for approximately 1 year, the need to report recurrence of symptoms, and the need for treating possible problems that occur after surgery, such as intolerance to dairy products and sweet foods.

**NURSING ALERT** The nurse reviews with the patient and family the signs and symptoms of complications to be reported. They include hemorrhage (cool skin, confusion, increased heart rate, labored breathing, and blood in the stool); penetration and perforation (severe abdominal pain, rigid and tender abdomen, vomiting, elevated temperature, and increased heart rate); pyloric obstruction (nausea, vomiting, distended abdomen, and abdominal pain). The nurse reviews with the patient and family the signs and symptoms of complications to be reported. They include hemorrhage (cool skin, confusion, increased heart rate, labored breathing, and blood in the stool); penetration and perforation (severe abdominal pain, rigid and tender abdomen, vomiting, elevated temperature, and increased heart rate); pyloric obstruction (nausea, vomiting, distended abdomen, and abdominal pain).

**Evaluation**

**EXPECTED PATIENT OUTCOMES**

Expected patient outcomes may include the following:

1. Reports freedom from pain between meals
2. Feels less anxiety by avoiding stress
3. Complies with therapeutic regimen
   a. Avoids irritating foods and beverages
   b. Eats regularly scheduled meals
   c. Takes prescribed medications as scheduled
   d. Uses coping mechanisms to deal with stress
4. Maintains weight
5. Is free of complications

**Morbid Obesity**

One in three Americans is 20% or more over his or her ideal body weight (U.S. Department of Health and Human Services, 2001). Morbid obesity is the term applied to people who are more than two times their ideal body weight or whose body mass index (BMI) exceeds 30 kg/m². (See Chapter 5.)

Another definition of morbid obesity is body weight that is more than 100 pounds greater than the ideal body weight (Monteforte & Turkelson, 2000). Patients with morbid obesity are at higher risk for health complications, such as cardiovascular disease, arthritis, asthma, bronchitis, and diabetes. They frequently suffer from low self-esteem, impaired body image, and depression.

**Medical Management**

Conservative management consists of placing the person on a weight loss diet in conjunction with behavioral modification and exercise; however, diet therapy is usually unsuccessful. There is a belief that depression may be a contributing factor to weight gain, and treatment of the depression with bupropion hydrochloride (Wellbutrin) may be helpful (Wangsness, 2000). Some physicians recommend acupuncture and hypnosis before recommending surgery.

**PHARMACOLOGIC MANAGEMENT**

Several medications have recently been approved for obesity. They include sibutramine HCl (Meridia) and orlistat (Xenical). By inhibiting the reuptake of serotonin and norepinephrine, sibutramine decreases appetite. Orlistat reduces caloric intake by binding to gastric and pancreatic lipase to prevent digestion of fats. Both medications require a physician’s prescription. Sibutramine may increase blood pressure and should not be taken by people with a history of coronary artery disease, angina pectoris, dysrhythmias, or kidney disease; by those taking antidepressants or monoamine oxidase inhibitors; or by pregnant or nursing women. Side effects may include dry mouth, insomnia, headache, increased sweating, and increased heart rate. Side effects of orlistat may include increased bowel movements, gas with oily discharge, decreased food absorption, decreased bile flow, and decreased absorption of some vitamins. A multivitamin is usually recommended for patients taking orlistat (Hussar, 2000).

**SURGICAL MANAGEMENT**

Bariatric surgery, or surgery for morbid obesity, is performed only after other nonsurgical attempts at weight control have failed. The first surgical procedure to treat morbid obesity was the jejunoileal bypass. This procedure, which resulted in significant
complications, has been largely replaced by gastric restriction procedures. Gastric bypass and vertical banded gastroplasty are the current operations of choice. These procedures may be performed laparoscopically or by an open surgical technique.

In gastric bypass surgery, the proximal segment of the stomach is transected to form a small pouch with a small gastroenterostomy stoma. The Roux-en-Y gastric bypass is the recommended procedure for long-term weight loss. In this procedure, a horizontal row of staples creates a stomach pouch with a 1-cm stoma that is anastomosed with a portion of distal jejunum, creating a gastroenterostomy. The transected proximal portion of the jejunum is anastomosed to the distal jejunum (Fig. 37-3A).

In vertical banded gastroplasty, a double row of staples is applied vertically along the lesser curvature of the stomach, beginning at the angle of His. A small stoma is created at the end of the staples by adding a circle of staples or a band of polypropylene mesh or silicone tubing (see Fig. 37-3B).

After weight loss, the patient may need surgical intervention for body contouring. This may include lipoplasty to remove fat deposits or a panniculectomy to remove excess abdominal skinfolds.

**Nursing Management**

Nursing management focuses on care of the patient after surgery. General postoperative nursing care is similar to that for a patient recovering from a gastric resection, but with attention given to the risks of complications associated with morbid obesity. Complications that may occur in the immediate postoperative period include peritonitis, stomal obstruction, stomal ulcers, atelectasis and pneumonia, thromboembolism, and metabolic imbalances resulting from prolonged vomiting and diarrhea. After bowel sounds have returned and oral intake is resumed, the nurse provides six small feedings consisting of a total of 600 to 800 calories per day and encourages fluid intake to prevent dehydration.

Patients are usually discharged in 4 to 5 days with detailed dietary instructions. The nurse instructs patients to report excessive thirst or concentrated urine, both of which are indications of dehydration. Psychosocial interventions are also essential for these patients. Efforts are directed toward helping them modify their eating behaviors and cope with changes in body image. The nurse explains that noncompliance by eating too much or too fast or eating high-calorie liquid and soft foods results in vomiting and painful esophageal distention. The nurse discusses dietary instructions before discharge and schedules monthly outpatient visits. Long-term side effects may include increased risk of gallstones, nutritional deficiencies, and potential to regain weight.

**Gastric Cancer**

The incidence of cancer of the stomach continues to decrease in the United States; however, it still accounts for 12,400 deaths annually (American Cancer Society, 2002). Most of these deaths occur in people older than 40 years of age, but they occasionally occur in younger people. Men have a higher incidence of gastric cancers than women do. The incidence of gastric cancer is much greater in Japan, which has instituted mass screening programs for earlier diagnosis. Diet appears to be a significant factor. A diet high in smoked foods and low in fruits and vegetables may increase the risk of gastric cancer. Other factors related to the incidence of gastric cancer include chronic inflammation of the stomach, pernicious anemia, achlorhydria, gastric ulcers, *H. pylori* infection, and genetics. The prognosis is poor, because most patients have metastases at the time of diagnosis (Greenlee, 2001).

![FIGURE 37-3](image-url) Surgical procedures for morbid obesity. (A) Gastric bypass with roux-en-Y. A horizontal row of staples creates a pouch with a capacity of 50 mL or less. The proximal jejunum is transected and the distal end anastomosed to the new pouch. The proximal segment is anastomosed to the jejunum. (B) Vertical banded gastroplasty. A vertical row of staples along the lesser curvature of the stomach creates a new, smaller stomach pouch of 10 to 15 mL.
Pathophysiology

Most gastric cancers are adenocarcinomas and can occur in any portion of the stomach. The tumor infiltrates the surrounding mucosa, penetrating the wall of the stomach and adjacent organs and structures. The liver, pancreas, esophagus, and duodenum are often affected at the time of diagnosis. Metastasis through lymph to the peritoneal cavity occurs later in the disease.

Clinical Manifestations

In the early stages of gastric cancer, symptoms may be absent. Early symptoms are seldom definitive because most gastric tumors begin on the lesser curvature, where they cause little disturbance of gastric functions. Some studies show that early symptoms, such as pain relieved with antacids, resemble those of benign ulcers. Symptoms of progressive disease may include anorexia, dyspepsia (indigestion), weight loss, abdominal pain, constipation, anemia, and nausea and vomiting.

Assessment and Diagnostic Findings

Usually the physical examination is not helpful in detecting cancer because most gastric tumors are not palpable. Ascites may be apparent if the cancer cells have metastasized to the liver. Endoscopy for biopsy and cytologic washings is the usual diagnostic study, and a barium x-ray examination of the upper GI tract may also be performed. Because metastasis often occurs before warning signs develop, a computed tomography (CT) scan, bone scan, and liver scan are valuable in determining the extent of metastasis. A complete x-ray examination of the GI tract should be performed when any person older than 40 years of age has had indigestion (dyspepsia) of more than 4 weeks’ duration.

Medical Management

There is no successful treatment for gastric carcinoma except removal of the tumor. If the tumor can be removed while it is still localized to the stomach, the patient can be cured. If the tumor has spread beyond the area that can be excised, cure is impossible. Palliative rather than radical surgery is performed if there is metastasis to other vital organs, such as the liver. In many of these patients, effective palliation to prevent discomfort caused by obstruction or dysphagia may be obtained by resection of the tumor (see Gastric Surgery).

If a radical subtotal gastrectomy is performed, the stump of the stomach is anastomosed to the jejunum, as in the gastroectomy for ulcer. When a total gastrectomy is performed, GI continuity is restored by means of an anastomosis between the ends of the esophagus and the jejunum.

If surgical treatment does not offer cure, treatment with chemotherapy may offer further control of the disease or palliation. Commonly used chemotherapeutic medications include cisplatin, irinotecan, or a combination of 5-fluorouracil, doxorubicin (Adriamycin), and mitomycin-C. Some studies are being conducted on the use of chemotherapy before surgery. Radiation therapy also may be used for palliation. Assessment of tumor markers (blood analysis for antigens indicative of colon cancer) such as carcinoembryonic antigen, CA 19-9, and CA 50 may help determine the effectiveness of treatment. If these values were elevated before treatment, they should decrease if the tumor is responding to the treatment (Bobbio-Pallavicini et al., 2001; Kerby & Heslin, 1999).

NURSING PROCESS: THE PATIENT WITH GASTRIC CANCER

Assessment

The nurse elicits a dietary history from the patient, focusing on recent nutritional intake and status. Has the patient lost weight? If so, how much and over what period of time? Can the patient tolerate a full diet? If not, what foods can he or she eat? What other changes in eating habits have occurred? Does the patient have an appetite? Is the patient in pain? Do foods, antacids, or medications relieve the pain, make no difference, or worsen the pain? Is there a history of infection with H. pylori bacteria? Other health information to obtain includes the patient’s smoking and alcohol history and the family history (any first- or second-degree relatives with gastric or other cancer). A psychosocial assessment, including questions about social support, individual and family coping skills, and financial resources, will help the nurse plan for care in acute and community settings.

After the interview, the nurse performs a complete physical examination, carefully assesses the patient’s abdomen for tenderness or masses, and also palpates and percusses to detect ascites.

Nursing Diagnosis

Based on the assessment data, the patient’s major nursing diagnoses may include the following:

- Anxiety related to the disease and anticipated treatment
- Imbalanced nutrition, less than body requirements, related to anorexia
- Pain related to tumor mass
- Anticipatory grieving related to the diagnosis of cancer
- Deficient knowledge regarding self-care activities

Planning and Goals

The major goals for the patient may include reduced anxiety, optimal nutrition, relief of pain, and adjustment to the diagnosis and anticipated lifestyle changes.

Nursing Interventions

REDUCING ANXIETY

A relaxed, nonthreatening atmosphere is provided so that patient can express fears, concerns, and possibly anger about the diagnosis and prognosis. The nurse encourages the family in their efforts to support the patient, offering reassurance and supporting positive coping measures. The nurse advises the patient about any procedures and treatments so that the patient knows what to expect. The nurse also may suggest talking with a support person (eg, spiritual advisor), if the patient desires.

PROMOTING OPTIMAL NUTRITION

The nurse encourages the patient to eat small, frequent portions of nonirritating foods to decrease gastric irritation. Food supplements should be high in calories, as well as vitamins A and C and iron, to enhance tissue repair. If the patient is unable to eat adequately to meet nutritional requirements, parenteral nutrition may be necessary. Because the patient may develop dumping syndrome when enteral feeding resumes after gastric resection, the nurse explains ways to prevent and manage it (six small feedings daily that are low in carbohydrates and sugar; fluids between meals rather than with meals) and informs the patient that symptoms often resolve after...
several months. If a total gastrectomy is performed, parenteral vitamin B$_{12}$ will be required indefinitely, because dietary vitamin B$_{12}$ is absorbed in the stomach. The nurse monitors the IV therapy and nutritional status and records intake, output, and daily weights to ensure that the patient is maintaining or gaining weight. The nurse assesses for signs of dehydration (thirst, dry mucous membranes, poor skin turgor, tachycardia, decreased urine output) and reviews the results of daily laboratory studies to note any metabolic abnormalities (sodium, potassium, glucose, blood urea nitrogen). Antiemetics are administered as prescribed.

**RELIEVING PAIN**
The nurse administers analgesics as prescribed. A continuous infusion of an opioid may be necessary for severe pain. The nurse assesses the frequency, intensity, and duration of the pain to determine the effectiveness of the analgesic being administered. The nurse works with the patient to manage pain by suggesting nonpharmacologic methods for pain relief, such as position changes, imagery, distraction, relaxation exercises (using relaxation audiotapes), backrubs, massage, and periods of rest and relaxation.

**PROVIDING PSYCHOSOCIAL SUPPORT**
The nurse helps the patient express fears, concerns, and grief about the diagnosis. It is important to answer the patient’s questions honestly and to encourage the patient to participate in treatment decisions. Some patients mourn the loss of a body part and perceive their surgery as a type of mutilation. Some express disbelief and need time and support to accept the diagnosis. The nurse offers emotional support and involves family members and significant others whenever possible. This includes recognizing mood swings and defense mechanisms (eg, denial, rationalization, displacement, regression) and reassuring the patient and family members that emotional responses are normal and expected. The services of clergy, psychiatric clinical nurse specialists, psychologists, social workers, and psychiatrists are made available, if needed. The nurse projects an empathetic attitude and spends time with the patient. Most patients will begin to participate in self-care activities after they have acknowledged their loss.

**PROMOTING HOME AND COMMUNITY-BASED CARE**

**Teaching Patients Self-Care**
Self-care activities will depend on the mode of treatment used—surgery, chemotherapy, radiation, or palliative care. Patient and family teaching will include information about diet and nutrition, treatment regimens, activity and lifestyle changes, pain management, and possible complications (Chart 37-3). Consultation with a dietician is essential to determine how the patient’s nutritional needs can best be met at home. The nurse teaches the patient or care provider about administration of enteral or parenteral nutrition. If chemotherapy or radiation is prescribed, the nurse provides explanations to the patient and family about what to expect, including the length of treatments, the expected side effects (eg, nausea, vomiting, anorexia, fatigue, neutropenia), and the need for transportation to appointments for treatment. Psychological counseling may also be helpful.

**Continuing Care**
The need for ongoing care in the home will depend on the patient’s condition and treatment. The home care nurse reinforces nutritional counseling and supervises the administration of any enteral or parenteral feedings; the patient or family member must become skillful in administering the feedings and in detecting and preventing untoward effects or complications related to the feedings (see Chapter 36 to review management of enteral and parenteral feedings). The nurse teaches the patient or a family member to record the patient’s daily intake, output, and weight and explains strategies to manage pain, nausea, vomiting, or other symptoms. The nurse also teaches the patient or caregiver to recognize and report signs and symptoms of complications that require medical attention, such as bleeding, obstruction, perforation, or any symptoms that become progressively worse. It is important to explain the chemotherapy or radiation therapy regimen. The patient and family need to know about the care that will be needed during and after treatments (see Chapter 16). Because the prognosis for gastric cancer is so poor, the nurse may need to assist the patient and family with decisions regarding end-of-life care. Referral to hospice may be warranted.

**Evaluation**

**EXPECTED PATIENT OUTCOMES**
Expected patient outcomes may include the following:

1. Reports less anxiety  
   - Expresses fears and concerns about surgery
2. Attains optimal nutrition  
   - Eats small, frequent meals high in calories, iron, and vitamins A and C
3. Has less pain
4. Performs self-care activities and adjusts to lifestyle changes  
   - Resumes normal activities within 3 months
   - Alternates periods of rest and activity
   - Manages tube feedings

Gastric Surgery

Gastric surgery may be performed on patients with peptic ulcers who have life-threatening hemorrhage, obstruction, perforation, or penetration or whose condition does not respond to medication. It also may be indicated for patients with gastric cancer or trauma. Surgical procedures include a vagotomy and pyloroplasty (disconnecting nerves that stimulate acid secretion and opening the pylorus), a partial gastrectomy, and a total gastrectomy (removal of the stomach) with either an end-to-end or an end-to-side esophagojejunostomy anastomosis (see Table 37-3).

NURSING PROCESS: THE PATIENT UNDERGOING GASTRIC SURGERY

Assessment

Before surgery, the nurse assesses the patient’s and family’s knowledge of preoperative and postoperative surgical routines and the rationale for surgery. The nurse also assesses the patient’s nutritional status: Has the patient lost weight? How much? Over how much time? Does the patient have nausea and vomiting? Has the patient had hematemesis? The nurse assesses for the presence of bowel sounds and palpates the abdomen to detect masses or tenderness.

After surgery, the nurse assesses the patient for complications secondary to the surgical intervention, such as hemorrhage, infection, abdominal distention, or decreased nutritional status. (See Chapters 20 and 25.)

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, the patient’s major nursing diagnoses may include the following:
- Anxiety related to surgical intervention
- Acute pain related to surgical incision
- Deficient knowledge about surgical procedures and postoperative course
- Imbalanced nutrition, less than body requirements, related to poor nutrition before surgery and altered GI system after surgery

COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

In addition to the complications to which all postoperative patients are subject, the patient undergoing gastric surgery is at increased risk for:
- Hemorrhage
- Dietary deficiencies
- Bile reflux
- Dumping syndrome

Planning and Goals

The major goals for the patient undergoing gastric surgery may include reduced anxiety, increased knowledge and understanding about the surgical procedure and postoperative course, optimal nutrition and management of the complications that can interfere with nutrition, relief of pain, avoidance of hemorrhage and steatorrhea, and enhanced self-care skills at home. General postoperative care for the patient who has received general anesthesia, as discussed in Chapter 20, should be followed.

Nursing Interventions

REDUCING ANXIETY

An important part of the preoperative nursing care involves allaying the patient’s fears and anxieties about the impending surgery and its implications. The nurse encourages the patient to express feelings and answers the patient’s and family’s questions. If the patient has an acute obstruction, a perforated bowel, or an active GI hemorrhage, adequate psychological preparation may not be possible. In this event, the nurse caring for the patient after surgery should anticipate the concerns, fears, and questions that are likely to surface and should be available for support and further explanations.

RELIEVING PAIN

After surgery, analgesics may be administered as prescribed to relieve pain and discomfort. It is important to avoid sedating the patient so as not to impair his or her ability to perform pulmonary care activities (deep breathing and coughing) and to ambulate. The nurse assesses the effectiveness of analgesic intervention. Positioning the patient in a Fowler’s position promotes comfort and allows emptying of the stomach after a partial gastrectomy.

The nurse maintains functioning of the NG tube to prevent distention and resultant pain and damage to the suture line. Normally, the amount of NG drainage after a total gastrectomy is small.

INCREASING KNOWLEDGE

The nurse explains routine preoperative and postoperative activities to the patient, which include preoperative medications, NG intubation, IV fluids, abdominal dressings, and pulmonary care. These explanations need to be reinforced after surgery, especially if the patient had emergency surgery.

RESUMING ENTERAL INTAKE

The patient’s nutritional status is evaluated before surgery, because many patients with gastric cancer are malnourished and may require preoperative enteral or, more often, parenteral nutrition (see Chapter 36). After surgery, parenteral nutrition may be continued to meet caloric needs, to replace fluids lost through drainage and vomitus, and to support the patient metabolically until oral intake is adequate.

After the return of bowel sounds and removal of the NG tube, the nurse may give fluids, followed by food in small portions. The nurse adds foods gradually until the patient is able to eat six small meals a day and drink 120 mL of fluid between meals. The key to increasing the dietary content is to offer food and fluids gradually as tolerated and to recognize that each patient’s tolerance is different.

RECOGNIZING OBSTACLES TO ADEQUATE NUTRITION

Dysphagia and Gastric Retention

Dysphagia may occur in patients who have had truncal vagotomy, a surgical procedure that can result in trauma to the lower esophagus. Gastric retention may be evidenced by abdominal distention, nausea, and vomiting. Regurgitation may also occur if the patient has eaten too much or too quickly. It also may indicate that edema along the suture line is preventing fluids and food from moving into the intestinal tract. If gastric retention occurs, it may be necessary to reinstate NG suction; pressure must be low to avoid disrupting the suture line.

Bile Reflux

Bile reflux gastritis and esophagitis may occur with the removal of the pylorus, which acts as a barrier to the reflux of duodenal contents. Burning epigastric pain and vomiting of bilious material manifest this condition. Eating or vomiting does not relieve the
situation. Agents that bind with bile acid, such as cholestyramine (Questran), may be helpful. Aluminum hydroxide gel (an antacid) and metoclopramide hydrochloride (Reglan) have been used with some success.

**Dumping Syndrome**

The term dumping syndrome refers to an unpleasant set of vasomotor and GI symptoms that sometimes occur in patients who have had gastric surgery or a form of vagotomy. It may be the mechanical result of surgery in which a small gastric remnant is connected to the jejunum through a large opening. Foods high in carbohydrates and electrolytes must be diluted in the jejunum before absorption can take place, but the passage of food from the stomach remnant into the jejunum is too rapid to allow this to happen. The symptoms that occur are probably a result of rapid distention of the jejunal loop anastomosed to the stomach. The hypertonic intestinal contents draw extracellular fluid from the circulating blood volume into the jejenum to dilute the high concentration of electrolytes and sugars. The ingestion of fluid at mealtime is another factor that causes the stomach contents to empty rapidly into the jejunum.

Early symptoms include a sensation of fullness, weakness, faintness, dizziness, palpitations, diaphoresis, cramping pains, and diarrhea. Later, there is a rapid elevation of blood glucose, followed by increased insulin secretion. This results in a reactive hypoglycemia, which also is unpleasant for the patient. Vasomotor symptoms that occur 10 to 90 minutes after eating are pallor, perspiration, palpitations, headache, and feelings of warmth, dizziness, and even drowsiness. Anorexia may also be a result of the dumping syndrome.

Steatorrhea also may occur in the patient with gastric surgery. It is partially the result of rapid gastric emptying, which prevents adequate mixing with pancreatic and biliary secretions. In mild cases, reducing the intake of fat and administering an antimitoty medication can control steatorrhea.

**Vitamin and Mineral Deficiencies**

Other dietary deficiencies the nurse should be aware of include malabsorption of organic iron, which may require supplementation with oral or parenteral iron, and a low serum level of vitamin B₁₂, which may require supplementation by the intramuscular route. Total gastrectomy results in a lack of intrinsic factor, a gastric secretion required for the absorption of vitamin B₁₂ from the GI tract. Unless this vitamin is supplied by parenteral injection after gastrectomy, the patient inevitably will suffer vitamin B₁₂ deficiency, which eventually leads to a condition identical to pernicious anemia. All manifestations of pernicious anemia, including macrocytic anemia and combined system disease, may be expected to develop within a period of 5 years or less; they progress in severity thereafter and, in the absence of therapy, are fatal. This complication is avoided by the regular monthly intramuscular injection of 100 to 1000 µg (usual dose is 300 µg) of vitamin B₁₂.

This regimen should be started without delay after gastrectomy. Weight loss is a common long-term problem because the patient experiences early fullness, which suppresses the appetite.

**TEACHING DIETARY SELF-MANAGEMENT**

Because the patient may experience any of the described conditions affecting nutrition, nursing intervention includes proper dietary instruction. The following teaching points are emphasized:

- To delay stomach emptying, the patient should assume a low Fowler’s position during mealtime, and after the meal the patient should lie down for 20 to 30 minutes.
- Antispasmodics, as prescribed, also may aid in delaying the emptying of the stomach.
- Fluid intake with meals is discouraged; instead, fluids may be consumed up to 1 hour before or 1 hour after mealtime.
- Meals should contain more dry items than liquid items.
- The patient can eat fat as tolerated but should keep carbohydrate intake low and avoid concentrated sources of carbohydrates.
- The patient should eat smaller but more frequent meals.
- Dietary supplements of vitamins and medium-chain triglycerides and injections of vitamin B₁₂ and iron may be prescribed.

The nurse also gives instructions regarding enteral or parenteral supplementation if it is needed.

**MONITORING AND MANAGING POTENTIAL Complications**

Occasionally hemorrhage complicates gastric surgery. The patient has the usual signs of rapid blood loss and shock (see Chapter 15) and may vomit considerable amounts of bright red blood. The nurse assesses NG drainage for type and amount; some bloody drainage for the first 12 hours is expected, but excessive bleeding should be reported. The nurse also assesses the abdominal dressing for bleeding. Because this situation is upsetting to the patient and family, the nurse should remain calm. The nurse performs emergency measures, such as NG lavage and administration of blood and blood products.

**PROMOTING HOME AND COMMUNITY-BASED CARE**

**Teaching Patients Self-Care**

Nurse-patient teaching stems from the assessment of the patient’s physical and psychological readiness to participate in self-care. The nurse provides information about nutrition, enteral or parenteral nutrition if required, nutritional supplements, pain management, and the symptoms of dumping syndrome and measures to use to prevent or minimize these symptoms (Chart 37–4). It is important to emphasize the continued need for vitamin B₁₂ injections.
Continuing Care
Both the patient and the family can benefit from a team approach
to discharge planning. The team members include the home care
nurse, physician, dietician, social worker, patient and family;
written instructions about meals, activities, medications, and
follow-up care are helpful. The home care nurse supervises the
administration of any enteral or parenteral feedings, emphasizing
information about detection and prevention of untoward effects or
complications related to the feedings. Information about community
support groups is provided to the patient and family.

Evaluation
EXPECTED PATIENT OUTCOMES
Expected patient outcomes may include:

1. Reports decreased anxiety; expresses fears and concerns about surgery
2. Demonstrates knowledge regarding postoperative course by discussing the surgical procedure and postoperative course
3. Attains optimal nutrition
   a. Maintains a reasonable weight
   b. Does not have excessive diarrhea
   c. Tolerates 6 small meals a day
   d. Does not experience dysphagia, gastric retention, bile reflux, dumping syndrome, or vitamin and mineral deficiencies
4. Attains optimal level of comfort
5. Has no evidence of hemorrhage

Critical Thinking Exercises

1. You are working in the office of a gastroenterologist. You have a patient coming in today with symptoms of a peptic ulcer. What questions will you ask the patient, and what types of teaching regimen do you anticipate you will need to review with this patient?

2. You are caring for a patient who is to have a gastrectomy to treat gastric cancer. What nutritional needs do you anticipate for this patient preoperatively, immediately postoperatively, and after discharge from the hospital?

3. Your 45-year-old patient who weighs 375 pounds has had gastric bypass to treat morbid obesity. Describe the preoperative interventions for this patient. How would you modify your interventions if the patient had diabetes? If he had angina?

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Identify the health care teaching needs of patients with constipation or diarrhea.
2. Compare the conditions of malabsorption with regard to their pathophysiology, clinical manifestations, and management.
3. Use the nursing process as a framework for care of patients with diverticulitis.
4. Compare regional enteritis and ulcerative colitis with regard to their pathophysiology, clinical manifestations, diagnostic evaluation, and medical, surgical, and nursing management.
5. Use the nursing process as a framework for care of the patient with an inflammatory bowel disease.
6. Describe the responsibilities of the nurse in meeting the needs of the patient with an ileostomy.
7. Describe the various types of intestinal obstructions and their management.
8. Use the nursing process as a framework for care of the patient with cancer of the colon or rectum.
9. Use the nursing process as a framework for care of the patient with an anorectal condition.
Diseases of the gastrointestinal (GI) tract account for about 10% of the total burden of illness in the United States. They account for more than 50 million office visits annually and nearly 10 million hospital admissions. GI diseases probably cost the American public up to $100 billion yearly and account for 10% of all deaths each year (Goldman & Bennett, 2000). The types of diseases and disorders that affect the lower GI tract are many and varied.

In all age groups, a fast-paced lifestyle, high levels of stress, irregular eating habits, insufficient intake of fiber and water, and lack of daily exercise contribute to GI problems. Nurses can have an impact on these chronic problems by identifying behavior patterns that put patients at risk, by educating the public about prevention and management, and by helping those affected to improve their condition and prevent complications.

Abnormalities of Fecal Elimination

Changes in patterns of fecal elimination are symptoms of functional disorders or disease of the GI tract. The most common changes seen are constipation, diarrhea, and fecal incontinence. The nurse should be aware of the possible causes and therapeutic management of these problems and of nursing management techniques. Education is important for patients with these abnormalities.

CONSTIPATION

Constipation is a term used to describe an abnormal infrequency or irregularity of defecation, abnormal hardening of stools that makes their passage difficult and sometimes painful, a decrease in stool volume, or retention of stool in the rectum for a prolonged period. Any variation from normal habits may be considered a problem.

Constipation can be caused by certain medications (ie, tranquilizers, anticholinergics, antidepressants, antihypertensives, opioids, antacids with aluminum, and iron); rectal or anal disorders (eg, hemorrhoids, fissures); obstruction (eg, cancer of the bowel); metabolic, neurologic, and neuromuscular conditions (eg, diabetes mellitus, Hirschsprung’s disease, Parkinson’s disease, multiple sclerosis); endocrine disorders (eg, hypothyroidism, pheochromocytoma); lead poisoning; and connective tissue disorders (eg, scleroderma, lupus erythematosus). Constipation is a major problem for patients taking opioids for chronic pain. Diseases of the colon commonly associated with constipation are irritable bowel syndrome (IBS) and diverticular disease. Constipation can also occur with an acute disease process in the abdomen (eg, appendicitis).

Other causes include weakness, immobility, debility, fatigue, and an inability to increase intra-abdominal pressure to facilitate the passage of stools, as occurs with emphysema. Many people develop constipation because they do not take the time to defecate or they ignore the urge to defecate. In the United States, constipation is also a result of dietary habits (ie, low consumption of fiber and inadequate fluid intake), lack of regular exercise, and a stress-filled life.

Perceived constipation can also be a problem. This subjective problem occurs when an individual’s bowel elimination pattern is not consistent with what he or she perceives as normal. Chronic laxative use is attributed to this problem and is a major health concern in the United States, especially among the elderly population.

Pathophysiology

The pathophysiology of constipation is poorly understood, but it is thought to include interference with one of three major functions of the colon: mucosal transport (ie, mucosal secretions facilitate the movement of colon contents), myoelectric activity (ie, mixing of the rectal mass and propulsive actions), or the processes of defecation. Any of the causative factors previously identified can interfere with any of these three processes.

The urge to defecate is stimulated normally by rectal distention, which initiates a series of four actions: stimulation of the inhibitory rectoanal reflex, relaxation of the internal sphincter muscle, relaxation of the external sphincter muscle and muscles in the pelvic region, and increased intra-abdominal pressure. Interference with any of these processes can lead to constipation.

If all organic causes are eliminated, idiopathic constipation is diagnosed. If the urge to defecate is ignored, the rectal mucous membrane and musculature become insensitive to the presence of fecal masses, and consequently, a stronger stimulus is required to produce the necessary peristaltic rush for defecation. The initial effect of fecal retention is to produce irritability of the colon, which at this stage frequently goes into spasm, especially after meals, giving rise to colicky midabdominal or low abdominal pains. After several years of this process, the colon loses muscular tone and becomes essentially unresponsive to normal stimuli. Atony or decreased muscle tone occurs with aging. This also leads to constipation because the stool is retained for longer periods.

Glossary

appendicitis: infectious and inflammatory process of the appendix creating acute abdominal pain and nausea
azotorrhea: excess of nitrogenous matter in the feces or urine
colostomy: surgical opening into the colon by means of a stoma to allow drainage of bowel contents; one type of fecal diversion
diverticulitis: inflammation of a diverticulum from obstruction (by fecal matter), resulting in abscess formation
diverticulosis: presence of a number of diverticula in the intestine; common in middle age
diverticulum: saclike outpouching of the lining of the bowel protruding through the muscle of the intestinal wall, usually caused by high intraluminal pressure
hemorrhoids: dilated portions of the anal veins; can occur internal or external to the anal sphincter ileostomy: surgical opening into the ileum by means of a stoma to allow drainage of bowel contents; one type of fecal diversion
inflammatory bowel disease: group of chronic disorders (most common are ulcerative colitis and regional enteritis [Crohn’s disease]) that result in inflammation or ulceration (or both) of the bowel lining, associated with abdominal pain, diarrhea, fever, and weight loss
irritable bowel syndrome: functional disorder that affects frequency of defecation and consistency of stool; associated with crampy abdominal pain and bloating
malabsorption: impaired transport across the mucosa
peritonitis: inflammation of the lining of the abdominal cavity, usually as a result of a bacterial infection of an area in the GI tract with leakage of contents into the abdominal cavity
Clinical Manifestations

Clinical manifestations include abdominal distention, borborygmus (ie, gurgling or rumbling sound caused by passage of gas through the intestine), pain and pressure, decreased appetite, headache, fatigue, indigestion, a sensation of incomplete emptying, straining at stool, and the elimination of small-volume, hard, dry stools.

Assessment and Diagnostic Findings

Chronic constipation is usually considered idiopathic, but secondary causes should be excluded. In patients with severe, intractable constipation, further diagnostic testing is needed (Wong, 1999). The diagnosis of constipation is based on results of the patient’s history, physical examination, possibly a barium enema or sigmoidoscopy, and stool testing for occult blood. These tests are performed to determine whether the symptom results from spasm or narrowing of the bowel. Anorectal manometry (ie, pressure studies) may be performed to determine malfunction of the muscle and sphincter. Defecography and bowel transit studies can also assist in the diagnosis (see Chap. 34).

Complications

Complications of constipation include hypertension, fecal impaction, hemorrhoids and fissures, and megacolon. Increased arterial pressure can occur with defecation. Straining at stool, which results in the Valsalva maneuver (ie, forcibly exhaling with the glottis closed), has a striking effect on arterial blood pressure. During active straining, the flow of venous blood in the chest is temporarily impeded because of increased intrathoracic pressure. This pressure tends to collapse the large veins in the chest. The atria and the ventricles receive less blood, and consequently less is delivered by the systemic contractions of the left ventricle. The cardiac output is decreased, and there is a transient drop in arterial pressure. Almost immediately after this period of hypotension, a rise in arterial pressure occurs; the pressure is elevated momentarily to a point far exceeding the original level (ie, rebound phenomenon). In patients with hypertension, this compensatory reaction may be exaggerated greatly, and the peaks of pressure attained may be dangerously high—sufficient to rupture a major artery in the brain or elsewhere.

Fecal impaction occurs when an accumulated mass of dry feces cannot be expelled. The mass may be palpable on digital examination, may produce pressure on the colonic mucosa that results in ulcer formation, and frequently may cause seepage of liquid stools.

Hemorrhoids and anal fissures can develop as a result of constipation. Hemorrhoids develop as a result of perianal vascular congestion caused by straining. Anal fissures may result from the passage of the hard stool through the anus, tearing the lining of the anal canal.

Megacolon is a dilated andatomiccoloned by a fecal mass that obstructs the passage of colon contents. Symptoms include constipation, liquid fecal incontinence, and abdominal distention. Megacolon can lead to perforation of the bowel.

Gerontologic Considerations

Physician visits for constipation are more frequent by individuals 65 years of age or older (Yamada et al., 1999). Elderly people report problems with constipation five times more frequently than younger people. A number of factors contribute to this increased frequency. People who have loose-fitting dentures or have lost their teeth have difficulty chewing and frequently choose soft, processed foods that are low in fiber. Convenience foods, also low in fiber, are widely used by those who have lost interest in eating. Some older people reduce their fluid intake if they are not eating regular meals. Lack of exercise and prolonged bed rest also contribute to constipation by decreasing abdominal muscle tone and intestinal motility as well as anal sphincter tone. Nerve impulses are dulled, and there is decreased sensation to defecation. Many older people who overuse laxatives in an attempt to have a daily bowel movement become dependent on them.

Medical Management

Treatment is aimed at the underlying cause of constipation and includes education, bowel habit training, increased fiber and fluid intake, and judicious use of laxatives. Management may also include discontinuing laxative abuse. Routine exercise to strengthen abdominal muscles is encouraged. Biofeedback is a technique that can be used to help patients learn to relax the sphincter mechanism to expel stool. Daily addition to the diet of 6 to 12 teaspoonfuls of unprocessed bran is recommended, especially for the treatment of constipation in the elderly. If laxative use is necessary, one of the following may be prescribed: bulk-forming agents, saline and osmotic agents, lubricants, stimulants, or fecal softeners. The physiologic action and patient education information related to these laxatives are identified in Table 38-1. Enemas and rectal suppositories are generally not recommended for constipation and should be reserved for the treatment of impaction or for preparing the bowel for surgery or diagnostic procedures. If long-term laxative use is necessary, a bulk-forming agent may be prescribed in combination with an osmotic laxative.

Doctors prescribe the use of specific medications to enhance colonic transit by increasing propulsive motor activity. Further studies are being carried out on cholinergic agents (eg, benzhexol), cholinesterase inhibitors (eg, neostigmine), and prokinetic agents (eg, metoclopramide) to determine the role these agents can play in treating constipation (Yamada et al., 1999).

Nursing Management

The nurse elicits information about the onset and duration of constipation, current and past elimination patterns, the patient’s expectation of normal bowel elimination, and lifestyle information (eg, exercise and activity level, occupation, food and fluid intake, and stress level) during the health history interview. Past medical and surgical history, current medications, and laxative and enema use are important, as is information about the sensation of rectal pressure or fullness, abdominal pain, excessive straining at defecation, and flatulence.

Patient education and health promotion are important functions of the nurse (Chart 38-1). After the health history is obtained, the nurse sets specific goals for teaching. Goals for the patient include restoring or maintaining a regular pattern of elimination, ensuring adequate intake of fluids and high-fiber foods, learning about methods to avoid constipation, relieving anxiety about bowel elimination patterns, and avoiding complications.

Diarrhea

Diarrhea is increased frequency of bowel movements (more than three per day), increased amount of stool (more than 200 g per day), and altered consistency (ie, looseness) of stool. It is usually associated with urgency, perianal discomfort, incontinence, or a combination of these factors. Any condition that causes increased intestinal secretions, decreased mucosal absorption, or altered
motility can produce diarrhea. Irritable bowel syndrome (IBS), inflammatory bowel disease (IBD), and lactose intolerance are frequently the underlying disease processes that cause diarrhea (Stone et al., 1999).

Diarrhea can be acute or chronic. Acute diarrhea is most often associated with infection and is usually self-limiting; chronic diarrhea persists for a longer period and may return sporadically. Diarrhea can be caused by certain medications (eg, thyroid hormone replacement, stool softeners and laxatives, antibiotics, chemotherapy, antacids), certain tube feeding formulas, metabolic and endocrine disorders (eg, diabetes, Addison’s disease, thyrotoxicosis), and viral or bacterial infectious processes (eg, dysentery, shigellosis, food poisoning). Other disease processes associated with diarrhea are nutritional and malabsorptive disorders (eg, celiac disease), anal sphincter defect, Zollinger-Ellison syndrome, paralytic ileus, intestinal obstruction, and acquired immunodeficiency syndrome (AIDS).

### Pathophysiology

Types of diarrhea include secretory, osmotic, and mixed diarrhea. Secretory diarrhea is usually high-volume diarrhea and is caused by increased production and secretion of water and electrolytes by the intestinal mucosa into the intestinal lumen. Osmotic diarrhea occurs when water is pulled into the intestines by the osmotic pressure of unabsorbed particles, slowing the reabsorption of water. Mixed diarrhea is caused by increased peristalsis (usually from IBD) and a combination of increased secretion and decreased absorption in the bowel. The physiology of diarrhea related to infection is discussed in Chapter 70.

### Clinical Manifestations

In addition to the increased frequency and fluid content of stools, the patient usually has abdominal cramps, distention, intestinal rumbling (ie, borborygmus), anorexia, and thirst. Painful spasmodic

<table>
<thead>

<th>CLASSIFICATION</th>
<th>SAMPLE AGENT</th>
<th>ACTION</th>
<th>PATIENT EDUCATION</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bulk forming</td>
<td>Psyllium hydrophilic mucilloid (Metamucil)</td>
<td>Polysaccharides and cellulose derivatives mix with intestinal fluids, swell, and stimulate peristalsis.</td>
<td>Take with 8 oz water and follow with 8 oz water; do not take dry. Report abdominal distention or unusual amount of flatulence.</td>
</tr>
<tr>
<td>Saline agent</td>
<td>Magnesium hydroxide (Milk of Magnesia)</td>
<td>Nonabsorbable magnesium ions alter stool consistency by drawing water into the intestines by osmosis; peristalsis is stimulated. Action occurs within 2 h.</td>
<td>The liquid preparation is more effective than the tablet form. Only short-term use is recommended because of toxicity (CNS or neuromuscular depression, electrolyte imbalance). Magnesium laxatives should not be taken by patients with renal insufficiency.</td>
</tr>
<tr>
<td>Lubricant</td>
<td>Mineral oil</td>
<td>Nonabsorbable hydrocarbons soften fecal matter by lubricating the intestinal mucosa; the passage of stool is facilitated. Action occurs within 6–8 h.</td>
<td>Do not take with meals, because mineral oils can impair the absorption of fat-soluble vitamins and delay gastric emptying. Swallow carefully, because drops of oil that gain access to the pharynx can produce a lipid pneumonia.</td>
</tr>
<tr>
<td>Stimulant</td>
<td>Bisacodyl (Dulcolax)</td>
<td>Irritates the colonic epithelium by stimulating sensory nerve endings and increasing mucosal secretions. Action occurs within 6–8 h.</td>
<td>Catharsis may cause fluid and electrolyte imbalance, especially in the elderly. Tablets should be swallowed, not crushed or chewed. Avoid milk or antacids within 1 hour of taking the medication, because the enteric coating may dissolve prematurely.</td>
</tr>
<tr>
<td>Fecal softener</td>
<td>Dioctyl sodium sulfosuccinate (Colace)</td>
<td>Hydrates the stool by its surfactant action on the colonic epithelium (increases the wetting efficiency of intestinal water); aqueous and fatty substances are mixed. Does not exert a laxative action.</td>
<td>Can be used safely by patients who should avoid straining (cardiac patients, patients with anorectal disorders).</td>
</tr>
<tr>
<td>Osmotic agent</td>
<td>Polyethylene glycol and electrolytes (Colyte)</td>
<td>Cleanses colon rapidly and induces diarrhea.</td>
<td>This is a large-volume product. It takes time to consume it safely. It can cause considerable nausea and bloating.</td>

**Chart 38-1**

Health Promotion: Preventing Constipation

- Describe the physiology of defecation.
- Emphasize the importance of heeding the urge to defecate.
- Discuss normal variations in patterns of defecation.
- Teach how to establish a bowel routine, and explain that having a regular time for defecation (eg, best time is after breakfast) may aid in initiating the reflex.
- Provide dietary information; suggest eating high-residue, high-fiber foods, adding bran daily (must be introduced gradually), and increasing fluid intake (unless contraindicated).
- Explain how an exercise regimen, increased ambulation, and abdominal muscle toning will increase muscle strength and help propel colon contents.
- Describe abdominal toning exercises (contracting abdominal muscles 4 times daily and leg-to-chest lifts 10 to 20 times each day).
- Explain that the normal position (semisquatting) maximizes use of abdominal muscles and force of gravity.
contractions of the anus and ineffectual straining (ie, tenesmus) may occur with dehydration. Other symptoms depend on the cause and severity of the diarrhea but are related to dehydration and to fluid and electrolyte imbalances.

Watery stools are characteristic of small bowel disease, whereas loose, semisolid stools are associated more often with disorders of the colon. Voluminous, greasy stools suggest intestinal malabsorption, and the presence of mucus and pus in the stools suggests inflammatory enteritis or colitis. Oil droplets on the toilet water are almost always diagnostic of pancreatic insufficiency. Nocturnal diarrhea may be a manifestation of diabetic neuropathy.

Assessment and Diagnostic Findings
When the cause of the diarrhea is not obvious, the following diagnostic tests may be performed: complete blood cell count, chemical profile, urinalysis, routine stool examination, and stool examinations for infectious or parasitic organisms, bacterial toxins, blood, fat, and electrolytes. Endoscopy or barium enema may assist in identifying the cause.

Complications
Complications of diarrhea include the potential for cardiac dysrhythmias because of significant fluid and electrolyte loss (especially loss of potassium). Urinary output of less than 30 mL per hour for 2 to 3 consecutive hours, muscle weakness, paresthesia, hypotension, anorexia, and drowsiness with a potassium level of less than 3.0 mEq/L (3 mmol/L) must be reported. Decreased potassium levels cause cardiac dysrhythmias (ie, atrial and ventricular tachycardia, ventricular fibrillation, and premature ventricular contractions) that can lead to death.

Medical Management
Primary management is directed at controlling symptoms, preventing complications, and eliminating or treating the underlying disease. Certain medications (eg, antibiotics, anti-inflammatory agents) may reduce the severity of the diarrhea and treat the underlying disease.

Nursing Management
The nurse’s role includes assessing and monitoring the characteristics and pattern of diarrhea. A health history addresses the patient’s medication therapy, medical and surgical history, and dietary patterns and intake. Reports of recent exposure to an acute illness or recent travel to another geographic area are important. Assessment includes abdominal auscultation and palpation for abdominal tenderness. Inspection of the abdomen and mucous membranes and skin is important to determine hydration status. Stool samples are obtained for testing.

During an episode of acute diarrhea, the nurse encourages bed rest and intake of liquids and foods low in bulk until the acute attack subsides. When food intake is tolerated, the nurse recommends a bland diet of semisolid and solid foods. The patient should avoid caffeine, carbonated beverages, and very hot and very cold foods, because they stimulate intestinal motility. It may be necessary to restrict milk products, fat, whole-grain products, fresh fruits, and vegetables for several days. The nurse administers antidiarrheal medications such as diphenoxylate (Lomotil) and loperamide (Imodium) as prescribed. Intravenous fluid therapy may be necessary for rapid rehydration, especially for the elderly and those with preexisting GI conditions (eg, IBD). It is important to closely monitor serum electrolyte levels. The nurse immediately reports evidence of dysrhythmias or a change in the level of consciousness.

NURSING ALERT Elderly persons can become dehydrated quickly and develop low potassium levels (ie, hypokalemia) as a result of diarrhea. The older person taking digitals must be aware of how quickly dehydration and hypokalemia can occur with diarrhea. The nurse instructs this person to recognize the signs of hypokalemia, because low levels of potassium intensify the action of digitals, which can lead to digitalis toxicity.

The perianal area may become excoriated because diarrheal stool contains digestive enzymes that can irritate the skin. The patient should follow a perianal skin care routine to decrease irritation and excoriation. It is important to use skin sealants and moisture barriers as needed. The older person’s skin is very sensitive because of decreased turgor and reduced subcutaneous fat layers.

Fecal Incontinence
The term fecal incontinence describes the involuntary passage of stool from the rectum. Several factors influence fecal continence—the ability of the rectum to sense and accommodate stool, the amount and consistency of stool, the integrity of the anal sphincters and musculature, and rectal motility.

Pathophysiology
Fecal incontinence can result from trauma (eg, after surgical procedures involving the rectum), a neurologic disorder (eg, stroke, multiple sclerosis, diabetic neuropathy, dementia), inflammation, infection, radiation treatment, fecal impaction, pelvic floor relaxation, laxative abuse, medications, or advancing age (ie, weakness or loss of anal or rectal muscle tone). It is an embarrassing and socially incapacitating problem that requires a many-tiered approach to treatment and much adaptation on the patient’s part.

Clinical Manifestations
Patients may have minor soiling, occasional urgency and loss of control, or complete incontinence. Patients may also experience poor control of flatus, diarrhea, or constipation.

Assessment and Diagnostic Findings
Diagnostic studies are necessary because the treatment of fecal incontinence depends on the cause. A rectal examination and other endoscopic examinations such as a flexible sigmoidoscopy are performed to rule out tumors, inflammation, or fissures. X-ray studies such as barium enema, computed tomography (CT) scans, anorectal manometry, and transit studies may be helpful in identifying alterations in intestinal mucosa and muscle tone or in detecting other structural or functional problems.

Medical Management
Although there is no known cause or cure for fecal incontinence, specific management techniques can help the patient achieve a better quality of life. If fecal incontinence is related to diarrhea,
the incontinence may disappear when diarrhea is successfully treated. Fecal incontinence is frequently a symptom of a fecal impaction. After the impaction is removed and the rectum is cleansed, normal functioning of the anorectal area can resume. If the fecal incontinence is related to a more permanent condition, other treatments are initiated. Biofeedback therapy can be of assistance if the problem is decreased sensory awareness or sphincter control. Bowel training programs can also be effective. Surgical procedures include surgical reconstruction, sphincter repair, or fecal diversion.

Nursing Management

The nurse takes a thorough health history, including information about previous surgical procedures, chronic illnesses, bowel habits and problems, and current medication regimen. The nurse also completes an examination of the rectal area.

The nurse initiates a bowel-training program that involves setting a schedule to establish bowel regularity. The goal is to assist the patient to achieve fecal continence. If this is not possible, the goal should be to manage the problem so the person can have predictable, planned elimination (Stone et al., 1999). Sometimes, it is necessary to use suppositories to stimulate the anal reflex. After the patient has achieved a regular schedule, the suppository can be discontinued. Biofeedback can be used in conjunction with these therapies to help the patient improve sphincter contractility and rectal sensitivity.

Fecal incontinence can also cause problems with perineal skin integrity. Maintaining skin integrity is a priority, especially in the debilitated or elderly patient. Incontinence briefs, although helpful in containing the fecal material, allow for increased skin contact with the feces and may cause excoriation of the skin. The nurse encourages and teaches meticulous skin hygiene.

Continence sometimes cannot be achieved, and the nurse assists the patient and family to accept and cope with this chronic situation. The patient can use fecal incontinence devices, which include external collection devices and internal drainage systems. External devices are special pouches that are drainable. They are attached to a synthetic adhesive skin barrier specially designed to conform to the buttocks. Internal drainage systems can be used to eliminate fecal skin contact and are especially useful when there is extensive excoriation or skin breakdown. A large catheter is inserted into the rectum and is connected to a drainage system.

IRRITABLE BOWEL SYNDROME

IBS is one of the most common GI problems. Approximately one in six otherwise healthy persons report classic symptoms of IBS (Wolfe, 2000). It occurs more commonly in women than in men, and the cause is still unknown. Although no anatomic or biochemical abnormalities have been found that explain the common symptoms, various factors are associated with the syndrome: heredity, psychological stress or conditions such as depression and anxiety, a diet high in fat and stimulating or irritating foods, alcohol consumption, and smoking. The small intestine has become a focus of investigation as an additional site of dysmotility in IBS, and cluster contractions in the jejunum and ileum are being studied (Wolfe, 2000). The diagnosis is made only after tests have been completed that prove the absence of structural or other disorders.

Pathophysiology

IBS results from a functional disorder of intestinal motility. The change in motility may be related to the neurologic regulatory system, infection or irritation, or a vascular or metabolic disturbance. The peristaltic waves are affected at specific segments of the intestine and in the intensity with which they propel the fecal matter forward. There is no evidence of inflammation or tissue changes in the intestinal mucosa.

Clinical Manifestations

There is a wide variability in symptom presentation. Symptoms range in intensity and duration from mild and infrequent to severe and continuous. The primary symptom is an alteration in bowel patterns—constipation, diarrhea, or a combination of both. Pain, bloating, and abdominal distention often accompany this change in bowel pattern. The abdominal pain is sometimes precipitated by eating and is frequently relieved by defecation.

Assessment and Diagnostic Findings

A definite diagnosis of IBS requires tests that prove the absence of structural or other disorders. Stool studies, contrast x-ray studies, and proctoscopy may be performed to rule out other colon diseases. Barium enema and colonoscopy may reveal spasm, distention, or mucus accumulation in the intestine (Fig. 38-1). Manometry and electromyography are used to study intraluminal pressure changes generated by spasticity.

Medical Management

The goals of treatment are aimed at relieving abdominal pain, controlling the diarrhea or constipation, and reducing stress. Restriction and then gradual reintroduction of foods that are possibly irritating may help determine what types of food are acting as irritants (e.g., beans, caffeinated products, fried foods, alcohol, spicy foods). A healthy, high-fiber diet is prescribed to help control the diarrhea and constipation. Exercise can assist in reducing anxiety and increasing intestinal motility. Patients often find it helpful to participate in a stress reduction or behavior-modification program.

FIGURE 38-1 In IBS, the spastic contractions of the bowel can be seen in x-ray contrast studies.
Hydrophilic colloids (ie, bulk) and antidiarrheal agents (eg, loperamide) may be given to control the diarrhea and fecal urgency. Antidepressants can assist in treating underlying anxiety and depression. Anticholinergics and calcium channel blockers decrease smooth muscle spasm, decreasing cramping and constipation.

**Nursing Management**

The nurse’s role is to provide patient and family education. The nurse emphasizes teaching and reinforces good dietary habits. The patient is encouraged to eat at regular times and to chew food slowly and thoroughly. The patient should understand that, although adequate fluid intake is necessary, fluid should not be taken with meals because this results in abdominal distention. Alcohol use and cigarette smoking are discouraged.

**CONDITIONS OF MALABSORPTION**

Malabsorption is the inability of the digestive system to absorb one or more of the major vitamins (especially vitamin B₁₂), minerals (ie, iron and calcium), and nutrients (ie, carbohydrates, fats, and proteins). Interruptions in the complex digestive process may occur anywhere in the digestive system and cause decreased absorption. Diseases of the small intestine are the most common cause of malabsorption.

**Pathophysiology**

The conditions that cause malabsorption can be grouped into the following categories:

- **Mucosal (transport) disorders causing generalized malabsorption** (eg, celiac sprue, regional enteritis, radiation enteritis)
- **Infectious diseases causing generalized malabsorption** (eg, small bowel bacterial overgrowth, tropical sprue, Whipple’s disease)
- **Luminal problems causing malabsorption** (eg, bile acid deficiency, Zollinger-Ellison syndrome, pancreatic insufficiency)
- **Postoperative malabsorption** (eg, after gastric or intestinal resection)
- **Disorders that cause malabsorption of specific nutrients** (eg, disaccharidase deficiency leading to lactose intolerance)

Table 38-2 lists the clinical and pathologic aspects of malabsorptive diseases.

**Clinical Manifestations**

The hallmarks of malabsorption syndrome from any cause are diarrhea or frequent, loose, bulky, foul-smelling stools that have increased fat content and are often grayish. Patients often have associated abdominal distention, pain, increased flatus, weakness, weight loss, and a decreased sense of well-being. The chief result of malabsorption is malnutrition, manifested by weight loss and other signs of vitamin and mineral deficiency (eg, easy bruising, osteoporosis, anemia). Patients with a malabsorption syndrome, if untreated, become weak and emaciated because of starvation and dehydration. Failure to absorb the fat-soluble vitamins A, D, and K causes a corresponding avitaminosis.

**Assessment and Diagnostic Findings**

Several diagnostic tests may be prescribed, including stool studies for quantitative and qualitative fat analysis, lactose tolerance tests, D-xylene absorption tests, and Schilling tests. The hydrogen breath test that is used to evaluate carbohydrate absorption (see Chap. 34) is performed if carbohydrate malabsorption is suspected. Endoscopy with biopsy of the mucosa is the best diagnostic tool. Biopsy of the small intestine is performed to assay enzyme activity or to identify infection or destruction of mucosa. Ultrasound studies, CT scans, and x-ray findings can reveal pancreatic or intestinal tumors that may be the cause. A complete blood cell count is used to detect anemia. Pancreatic function tests can assist in the diagnosis of specific disorders.

**Medical Management**

Intervention is aimed at avoiding dietary substances that aggravate malabsorption and at supplementing nutrients that have been lost. Common supplements are water-soluble vitamins (eg, B₁₂, folic acid), fat-soluble vitamins (ie, A, D, and K), and minerals (eg, calcium, iron). Primary disease states may be managed surgically or nonsurgically. Dietary therapy is aimed at reducing gluten intake in patients with celiac sprue. Folic acid supplements are prescribed for patients with tropical sprue. Antibiotics (eg, tetracycline, ampicillin) are sometimes needed in the treatment of tropical sprue and bacterial overgrowth syndromes. Antidiarrheal agents may be used to decrease intestinal spasms. Parenteral fluids may be necessary to treat dehydration.

**Nursing Management**

The nurse provides patient and family education regarding diet and the use of nutritional supplements (Chart 38-2). It is important to monitor patients with diarrhea for fluid and electrolyte imbalances. The nurse conducts ongoing assessments to determine if the clinical manifestations related to the nutritional deficits have abated. Patient education includes information about the risk of osteoporosis related to malabsorption of calcium.

**Acute Inflammatory Intestinal Disorders**

Any part of the lower GI tract is susceptible to acute inflammation caused by bacterial, viral, or fungal infection. Two such situations are appendicitis and diverticulitis. These two conditions can lead to peritonitis, an inflammatory process within the abdomen.

**APPENDICITIS**

The appendix is a small, finger-like appendage about 10 cm (4 in) long that is attached to the cecum just below the ileocecal valve. The appendix fills with food and empties regularly into the cecum. Because it empties inefficiently and its lumen is small, the appendix is prone to obstruction and is particularly vulnerable to infection (ie, appendicitis).

**Appendicitis**, the most common cause of acute abdomen in the United States, is the most common reason for emergency abdominal surgery. About 7% of the population will have appendicitis at some time in their lives; males are affected more than females, and teenagers more than adults. Although it can occur at any age, it occurs most frequently between the ages of 10 and 30 years (Yamada et al., 1999).

**Pathophysiology**

The appendix becomes inflamed and edematous as a result of either becoming kinked or occluded by a fecalith (ie, hardened mass of stool), tumor, or foreign body. The inflammatory process
increases intraluminal pressure, initiating a progressively severe, generalized or upper abdominal pain that becomes localized in the right lower quadrant of the abdomen within a few hours. Eventually, the inflamed appendix fills with pus.

**Clinical Manifestations**

Vague epigastric or periumbilical pain progresses to right lower quadrant pain and is usually accompanied by a low-grade fever and nausea and sometimes by vomiting. Loss of appetite is common. Local tenderness is elicited at McBurney’s point when pressure is applied (Fig. 38-2). Rebound tenderness (ie, production of pain when pressure is released) may be present. The extent of tenderness and muscle spasm and the existence of constipation or diarrhea depend not so much on the severity of the appendiceal infection as on the location of the appendix. If the appendix curls around behind the cecum, pain and tenderness may be felt in the lumbar region. If its tip is in the pelvis, these signs may be elicited only on rectal examination. Pain on defecation suggests that the tip of the appendix is resting against the rectum; pain on urination suggests that the tip is near the bladder or impinges on the ureter. Some rigidity of the lower portion of the right rectus muscle may occur. Rovsing’s sign may be elicited by palpating the left lower quadrant; this paradoxically causes pain to be felt in the right lower quadrant (see Fig. 38-2). If the appendix has ruptured, the pain becomes more diffuse; abdominal distention develops as a result of paralytic ileus, and the patient’s condition worsens.

**Assessment and Diagnostic Findings**

Diagnosis is based on results of a complete physical examination and on laboratory and x-ray findings. The complete blood cell count demonstrates an elevated white blood cell count. The leukocyte...
count may exceed 10,000 cells/mm³, and the neutrophil count may exceed 75%. Abdominal x-ray films, ultrasound studies, and CT scans may reveal a right lower quadrant density or localized distention of the bowel.

Complications

The major complication of appendicitis is perforation of the appendix, which can lead to peritonitis or an abscess. The incidence of perforation is 10% to 32%. The incidence is higher in young children and the elderly. Perforation generally occurs 24 hours after the onset of pain. Symptoms include a fever of 37.7°C (100°F) or higher, a toxic appearance, and continued abdominal pain or tenderness.

Gerontologic Considerations

Acute appendicitis does not occur frequently in the elderly population. Classic signs and symptoms are altered and may vary greatly. Pain may be absent or minimal. Symptoms may be vague, suggesting bowel obstruction or another process. Fever and leukocytosis may not be present. As a result, diagnosis and prompt treatment may be delayed, causing potential complications and mortality. The patient may have no symptoms until the appendix ruptures. The incidence of perforated appendix is higher in the elderly population because many of these patients do not seek health care as quickly as younger patients.

Medical Management

Surgery is indicated if appendicitis is diagnosed. To correct or prevent fluid and electrolyte imbalance and dehydration, antibiotics and intravenous fluids are administered until surgery is performed. Analgesics can be administered after the diagnosis is made. Appendectomy (ie, surgical removal of the appendix) is performed as soon as possible to decrease the risk of perforation. It may be performed under a general or spinal anesthetic with a low abdominal incision or by laparoscopy.

Nursing Management

Goals include relieving pain, preventing fluid volume deficit, reducing anxiety, eliminating infection from the potential or actual disruption of the GI tract, maintaining skin integrity, and attaining optimal nutrition.

The nurse prepares the patient for surgery, which includes an intravenous infusion to replace fluid loss and promote adequate renal function and antibiotic therapy to prevent infection. If there is evidence or likelihood of paralytic ileus, a nasogastric tube is inserted. An enema is not administered because it can lead to perforation.

After surgery, the nurse places the patient in a semi-Fowler position. This position reduces the tension on the incision and abdominal organs, helping to reduce pain. An opioid, usually morphine sulfate, is prescribed to relieve pain. When tolerated, oral fluids are administered. Any patient who was dehydrated before surgery receives intravenous fluids. Food is provided as desired and tolerated on the day of surgery.

The patient may be discharged on the day of surgery if the temperature is within normal limits, there is no undue discomfort in the operative area, and the appendectomy was uncomplicated. Discharge teaching for the patient and family is imperative. The nurse instructs the patient to make an appointment to have the surgeon remove the sutures between the fifth and seventh days after surgery. Incision care and activity guidelines are discussed; normal activity can usually be resumed within 2 to 4 weeks.

If there is a possibility of peritonitis, a drain is left in place at the area of the incision. Patients at risk for this complication may be kept in the hospital for several days and are monitored carefully for signs of intestinal obstruction or secondary hemorrhage. Secondary abscesses may form in the pelvis, under the diaphragm, or...
in the liver, elevating the temperature and pulse rate and increasing the leukocyte count.

When the patient is ready for discharge, the nurse teaches the patient and family to care for the incision and perform dressing changes and irrigations as prescribed. A home care nurse may be needed to assist with this care and to monitor the patient for complications and wound healing. Other potential complications of appendectomy are listed in Table 38-3.

DIVERTICULAR DISEASE

A diverticulum is a saclike outpouching of the lining of the bowel that extends through a defect in the muscle layer. Diverticula may occur anywhere along the GI tract. Diverticulosis exists when multiple diverticula are present without inflammation or symptoms. Diverticular disease of the colon is very common in developed countries, and its prevalence increases with age. More than 35% of Americans older than 60 years of age have diverticulosis. The incidence increases to 50% among those in the ninth decade of life (Keighley, 1999). Diverticulitis results when food and bacteria retained in a diverticulum produce infection and inflammation that can impede drainage and lead to perforation or abscess formation. Diverticulitis is most common (95%) in the sigmoid colon. Approximately 20% of patients with diverticulosis have diverticulitis at some point. A congenital predisposition is suspected when the disorder occurs in those younger than 40 years of age. A low intake of dietary fiber is considered a predisposing factor, but the exact cause is unknown. Diverticulitis may occur in acute attacks or may persist as a continuing, smoldering infection. Most patients remain entirely asymptomatic. The symptoms manifested generally result from its potential complications—abscesses, fistulas, obstruction, and hemorrhage.

Pathophysiology

A diverticulum forms when the mucosa and submucosal layers of the colon herniate through the muscular wall because of high intraluminal pressure, low volume in the colon (ie, fiber-deficient contents), and decreased muscle strength in the colon wall (ie, muscular hypertrophy from hardened fecal masses). Bowel contents can accumulate in the diverticulum and decompose, causing inflammation and infection. A diverticulum can become obstructed and then inflamed if the obstruction continues. The inflammation tends to spread to the surrounding bowel wall, giving rise to irritability and spasticity of the colon (ie, diverticulitis). Abscesses develop and may eventually perforate, leading to peritonitis and erosion of the blood vessels (arterial) with bleeding.

Clinical Manifestations

Chronic constipation often precedes the development of diverticulosis by many years. Frequently, no problematic symptoms occur with diverticulosis. Signs of acute diverticulitis are bowel irregularity and intervals of diarrhea, abrupt onset of crampy pain in the left lower quadrant of the abdomen, and a low-grade fever. The patient may have nausea and anorexia, and some bloating or abdominal distention may occur. With repeated local inflammation of the diverticula, the large bowel may narrow with fibrotic strictures, leading to cramps, narrow stools, and increased constipation. Weakness, fatigue, and anorexia are common symptoms. With acute diverticulitis, the patient reports mild to severe pain in the lower left quadrant. The condition, if untreated, can lead to septicemia.

Assessment and Diagnostic Findings

A CT scan is the procedure of choice and can reveal abscesses. Abdominal x-ray findings may demonstrate free air under the diaphragm if a perforation has occurred from the diverticulitis. Diverticulosis may be diagnosed using barium enema, which shows narrowing of the colon and thickened muscle layers. If there are symptoms of peritoneal irritation and when the diagnosis is diverticulitis, barium enema is contraindicated because of the potential for perforation.

A colonoscopy may be performed if there is no acute diverticulitis or after resolution of an acute episode to visualize the colon, determine the extent of the disease, and rule out other conditions. Laboratory tests that assist in diagnosis include a complete blood cell count, revealing an elevated leukocyte count, and elevated sedimentation rate.

Complications

Complications of diverticulitis include peritonitis, abscess formation, and bleeding. If an abscess develops, the associated findings are tenderness, a palpable mass, fever, and leukocytosis. An inflamed diverticulum that perforates results in abdominal pain localized over the involved segment, usually the sigmoid; local abscess or peritonitis follows. Abdominal pain, a rigid boardlike abdomen, loss of bowel sounds, and signs and symptoms of shock occur with peritonitis. Noninflamed or slightly inflamed diverticula may erode areas adjacent to arterial branches, causing massive rectal bleeding.

Gerontologic Considerations

The incidence of diverticular disease increases with age because of degeneration and structural changes in the circular muscle layers of the colon and because of cellular hypertrophy. The symptoms are less pronounced in the elderly than in other adults. The elderly may not have abdominal pain until infection occurs. They may delay reporting symptoms because they fear surgery or are afraid that they may have cancer. Blood in the stool is overlooked frequently, especially in the elderly, because of a failure to examine the stool or the inability to see changes because of diminished vision.

Medical Management

Dietary and Medication Management

Diverticulitis can usually be treated on an outpatient basis with diet and medicine therapy. When symptoms occur, rest, analgesics, and antispasmodics are recommended. Initially, the diet is clear fluid until the inflammation subsides; then, a high-fiber, low-fat diet is recommended. This type of diet helps to increase stool volume, decrease colonic transit time, and reduce intraluminal pressure. Antibiotics are prescribed for 7 to 10 days. A bulk-forming laxative also is prescribed.

In acute cases of diverticulitis with significant symptoms, hospitalization is required. Hospitalization is often indicated for those who are elderly, immunocompromised, or taking corticosteroids. Withholding oral intake, administering intravenous fluids, and instituting nasogastric suctioning if vomiting or distention occurs rests the bowel. Broad-spectrum antibiotics are prescribed for 7 to 10 days. An opioid is prescribed for pain relief; morphine is not used because it increases segmentation and intraluminal pressures. Oral intake is increased as symptoms subside. A low-fiber diet may be necessary until signs of infection decrease.

Antispasmodics such as propantheline bromide (Pro-Banthine) and oxyphenbutamine (Daricon) may be prescribed. Normal stools can be achieved by using bulk preparations (Metamucil) or stool softeners (Colace), by instilling warm oil into the rectum, or by inserting an evacuant suppository (Dulcolax). Such a prophylactic plan can reduce the bacterial flora of the bowel, diminish the bulk of the stool, and soften the fecal mass so that it moves more easily through the area of inflammatory obstruction.

Surgical Management

Although acute diverticulitis usually subsides with medical management, immediate surgical intervention is necessary if complications (eg, perforation, peritonitis, abscess formation, hemorrhage, obstruction) occur. Alternatively, when the acute episode of diverticulitis resolves, surgery may be recommended to prevent repeated episodes. Two types of surgery are considered:

- One-stage resection in which the inflamed area is removed and a primary end-to-end anastomosis is completed
- Multiple-staged procedures for complications such as obstruction or perforation (Fig. 38-3)

The type of surgery performed depends on the extent of complications found during surgery. When possible, the area of diverticulitis is resected and the remaining bowel is joined end to end (ie, primary resection and end-to-end anastomosis). This is performed through traditional surgical or laparoscopically assisted colectomy. A two-stage resection may be performed in which the diseased colon is resected (as in a one-stage procedure) but no anastomosis is performed; both ends of the bowel are brought out onto the abdomen as stomas. This “double-barrel” colostomy is then reanastomosed in a later procedure. Fecal diversion procedures are discussed later in this chapter.

NURSING PROCESS: THE PATIENT WITH DIVERTICULITIS

Assessment

During the health history, the nurse asks the patient about the onset and duration of pain and about past and present elimination patterns. The nurse reviews dietary habits to determine fiber intake and asks the patient about straining at stool, stool softeners (Colace), by instilling warm oil into the rectum, or by inserting an evacuant suppository (Dulcolax). Such a prophylactic plan can reduce the bacterial flora of the bowel, diminish the bulk of the stool, and soften the fecal mass so that it moves more easily through the area of inflammatory obstruction.

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, the nursing diagnoses may include the following:

- Constipation related to narrowing of the colon from thickened muscular segments and strictures
- Acute pain related to inflammation and infection

NURSING DIAGNOSES

Based on the assessment data, the nursing diagnoses may include the following:

- Constipation related to narrowing of the colon from thickened muscular segments and strictures
- Acute pain related to inflammation and infection

![Figure 38-3](image-url) The Hartmann procedure for diverticulitis: primary resection for diverticulitis of the colon. The affected segment (clamp attached) has been divided at its distal end. In a primary anastomosis, the proximal margin (dotted line) is transected and the bowel attached end-to-end. In a two-stage procedure, a colostomy is constructed at the proximal margin with the distal stump oversewn (Hartmann procedure, as shown) or brought to the outer surface as a mucous fistula. The second stage consists of colostomy takedown and anastomosis.
COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS
Potential complications that may develop include the following:

- Peritonitis
- Abscess formation
- Bleeding

Planning and Goals
The major goals for the patient may include attainment and maintenance of normal elimination patterns, pain relief, and absence of complications.

Nursing Interventions

MAINTAINING NORMAL ELIMINATION PATTERNS
The nurse recommends a fluid intake of 2 L per day (within limits of the patient’s cardiac and renal reserve) and suggests foods that are soft but have increased fiber to increase the bulk of the stool and facilitate peristalsis, thereby promoting defecation. An individualized exercise program is encouraged to improve abdominal muscle tone. It is important to review the patient’s daily routine to establish a schedule for meals and a set time for defecation and to assist in identifying habits that may have suppressed the urge to defecate. The nurse encourages daily intake of bulk laxatives such as Metamucil, which helps to propel feces through the colon. Stool softeners are administered as prescribed to decrease straining at stool, which decreases intestinal pressure. Oil retention enemas may be prescribed to soften the stool, making it easier to pass.

RELIEVING PAIN
Analgesics (eg, meperidine) to relieve the pain of diverticulitis and antispasmodic agents to decrease intestinal spasm are administered as prescribed. The nurse records the intensity, duration, and location of pain to determine if the inflammatory process worsens or subsides.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS
The major nursing focus is to prevent complications by identifying patients at risk and managing their symptoms as needed. The nurse assesses for the following signs of perforation:

- Increased abdominal pain and tenderness accompanied by abdominal rigidity
- Elevated white blood cell count
- Elevated sedimentation rate
- Increased temperature
- Tachycardia
- Hypotension

Perforation is a surgical emergency. The clinical manifestations of perforation and peritonitis and the care of the patient with peritonitis are presented in the next section. The nurse monitors vital signs and urine output and administers intravenous fluids to replace volume loss as needed.

HOME AND COMMUNITY-BASED CARE
Because patients and their family members and health care providers tend to focus on the most obvious needs and issues, the nurse reminds the patient and family about the importance of continuing health promotion and screening practices. The nurse educates patients who have not been involved in these practices in the past about their importance and refers the patients to appropriate health care providers.

Evaluation

EXPECTED PATIENT OUTCOMES
Expected patient outcomes may include the following:

1. Attains a normal pattern of elimination
   a. Reports less abdominal cramping and pain
   b. Reports the passage of soft, formed stool without pain
   c. Adds unprocessed bran to foods
   d. Drinks at least 10 glasses of fluid each day (if fluid intake is tolerated)
   e. Exercises daily
2. Reports decreased pain
   a. Requests analgesics as needed
   b. Adheres to a low-fiber diet during acute episodes
3. Recovers without complications
   a. Is afebrile
   b. Has normal blood pressure
   c. Has a soft, nontender abdomen with normal bowel sounds
   d. Maintains adequate urine output
   e. Has no blood in the stool

PERITONITIS
Peritonitis is inflammation of the peritoneum, the serous membrane lining the abdominal cavity and covering the viscera. Usually, it is a result of bacterial infection; the organisms come from diseases of the GI tract or, in women, from the internal reproductive organs. Peritonitis can also result from external sources such as injury or trauma (eg, gunshot wound, stab wound) or an inflammation that extends from an organ outside the peritoneal area, such as the kidney. The most common bacteria implicated are Escherichia coli, Klebsiella, Proteus, and Pseudomonas. Inflammation and paralytic ileus are the direct effects of the infection. Other common causes of peritonitis are appendicitis, perforated ulcer, diverticulitis, and bowel perforation (Fig. 38-4). Peritonitis may also be associated with abdominal surgical procedures and peritoneal dialysis.

**Figure 38-4** Common gastrointestinal causes of peritonitis.
Pathophysiology

Peritonitis is caused by leakage of contents from abdominal organs into the abdominal cavity, usually as a result of inflammation, infection, ischemia, trauma, or tumor perforation. Bacterial proliferation occurs. Edema of the tissues results, and exudation of fluid develops in a short time. Fluid in the peritoneal cavity becomes turbid with increasing amounts of protein, white blood cells, cellular debris, and blood. The immediate response of the intestinal tract is hypermotility, soon followed by paralytic ileus with an accumulation of air and fluid in the bowel.

Clinical Manifestations

Symptoms depend on the location and extent of the inflammation. The early clinical manifestations of peritonitis frequently are the symptoms of the disorder causing the condition. At first, a diffuse type of pain is felt. The pain tends to become constant, localized, and more intense near the site of the inflammation. Movement usually aggravates it. The affected area of the abdomen becomes extremely tender and distended, and the muscles become rigid. Rebound tenderness and paralytic ileus may be present. Usually, nausea and vomiting occur and peristalsis is diminished. The temperature and pulse rate increase, and there is almost always an elevation of the leukocyte count.

Assessment and Diagnostic Findings

The leukocyte count is elevated. The hemoglobin and hematocrit levels may be low if blood loss has occurred. Serum electrolyte studies may reveal altered levels of potassium, sodium, and chloride.

An abdominal x-ray is obtained, and findings may show air and fluid levels as well as distended bowel loops. A CT scan of the abdomen may show abscess formation. Peritoneal aspiration and culture and sensitivity studies of the aspirated fluid may reveal infection and identify the causative organisms.

Complications

Frequently, the inflammation is not localized and the whole abdominal cavity becomes involved in a generalized sepsis. Sepsis is the major cause of death from peritonitis. Shock may result from septicemia or hypovolemia. The inflammatory process may cause intestinal obstruction, primarily from the development of bowel adhesions.

The two most common postoperative complications are wound evisceration and abscess formation. Any suggestion from the patient that an area of the abdomen is tender or painful or “feels as if something just gave way” must be reported. The sudden occurrence of serosanguineous wound drainage strongly suggests wound dehiscence (see Chap. 20).

Medical Management

Fluid, colloid, and electrolyte replacement is the major focus of medical management. The administration of several liters of an isotonic solution is prescribed. Hypovolemia occurs because massive amounts of fluid and electrolytes move from the intestinal lumen into the peritoneal cavity and deplete the fluid in the vascular space.

Analgesics are prescribed for pain. Antiemetics are administered as prescribed for nausea and vomiting. Intestinal intubation and suction assist in relieving abdominal distention and in promoting intestinal function. Fluid in the abdominal cavity can cause pressure that restricts expansion of the lungs and causes respiratory distress. Oxygen therapy by nasal cannula or mask can promote adequate oxygenation, but airway intubation and ventilatory assistance occasionally are required.

Massive antibiotic therapy is usually initiated early in the treatment of peritonitis. Large doses of a broad-spectrum antibiotic are administered intravenously until the specific organism causing the infection is identified and the appropriate antibiotic therapy can be initiated.

Surgical objectives include removing the infected material and correcting the cause. Surgical treatment is directed toward excision (ie, appendix), resection with or without anastomosis (ie, intestine), repair (ie, perforation), and drainage (ie, abscess). With extensive sepsis, a fecal diversion may need to be created.

Nursing Management

Ongoing assessment of pain, vital signs, GI function, and fluid and electrolyte balance is important. The nurse reports the nature of the pain, its location in the abdomen, and any shifts in location. Administering analgesic medication and positioning the patient for comfort are helpful in decreasing pain. The patient is placed on the side with knees flexed; this position decreases tension on the abdominal organs. Accurate recording of all intake and output and central venous pressure assists in calculating fluid replacement. The nurse administers and monitors closely intravenous fluids.

Signs that indicate peritonitis is subsiding include a decrease in temperature and pulse rate, softening of the abdomen, return of peristaltic sounds, passing of flatus, and bowel movements. The nurse increases fluid and food intake gradually and reduces parenteral fluids as prescribed. A worsening clinical condition may indicate a complication, and the nurse must prepare the patient for emergency surgery.

Drains are frequently inserted during the surgical procedure, and the nurse must observe and record the character of the drainage postoperatively. Care must be taken when moving and turning the patient to prevent the drains from being dislodged. It is also important for the nurse to prepare the patient and family for discharge by teaching the patient to care for the incision and drains if the patient will be sent home with the drains still in place.

Inflammatory Bowel Disease

The term inflammatory bowel disease refers to two chronic inflammatory GI disorders: regional enteritis (ie, Crohn’s disease or granulomatous colitis) and ulcerative colitis. Both disorders have striking similarities but also several differences. Table 38-4 compares regional enteritis and ulcerative colitis.

The incidence of IBD in the United States has increased in the past century; 10,000 to 15,000 new cases occur annually (Yamada et al., 1999). In the past, a higher rate was observed among Caucasians in general and the Jewish population in particular. Data now indicate a higher risk for African Americans and a lower risk for Jewish people, and women appear to be at higher risk than before. People between the ages of 10 and 30 are at greatest risk.

Despite vast amounts of research, the cause of IBD is still unknown. Researchers think it is triggered by environmental agents such as pesticides, food additives, tobacco, and radiation (Kirsner & Shorter, 2000). Nonsteroidal anti-inflammatory drugs have been found to exacerbate IBD. Allergies and immune disorders have also been suggested as causes. Abnormal response to dietary
or bacterial antigens has been studied extensively, and genetic factors also are being studied. There is a high prevalence of coexistent IBS, which complicates the overall symptom presentation.

**REGIONAL ENTERITIS (CROHN’S DISEASE)**

Regional enteritis commonly occurs in adolescents or young adults but can appear at any time of life. It is more common in women, and it occurs frequently in the older population (between the ages of 50 and 80). It can occur anywhere along the GI tract, but the most common areas are the distal ileum and colon. The incidence of Crohn’s disease has risen over the past 30 years. Crohn’s disease is seen two times more often in patients who smoke than in nonsmokers (Rose, 1998).

### Pathophysiology

Regional enteritis is a subacute and chronic inflammation that extends through all layers (ie, transmural lesion) of the bowel wall from the intestinal mucosa. It is characterized by periods of remissions and exacerbations. The disease process begins with edema and thickening of the mucosa. Ulcers begin to appear on the inflamed mucosa. These lesions are not in continuous contact with one another and are separated by normal tissue. Fistulas, fissures, and abscesses form as the inflammation extends into the peritoneum. Granulomas occur in one half of patients. In advanced cases, the intestinal mucosa has a cobblestone appearance. As the disease advances, the bowel wall thickens and becomes fibrotic, and the intestinal lumen narrows. Diseased bowel loops sometimes adhere to other loops surrounding them.

</table>
Clinical Manifestations

In regional enteritis, the onset of symptoms is usually insidious, with prominent lower right quadrant abdominal pain and diarrhea unrelied by defecation. Scar tissue and the formation of granulomas interfere with the ability of the intestine to transport products of the upper intestinal digestion through the constricted lumen, resulting in crampy abdominal pains. There is abdominal tenderness and spasm. Because eating stimulates intestinal peristalsis, the crampy pains occur after meals. To avoid these bouts of crampy pain, the patient tends to limit food intake, reducing the amounts and types of food to such a degree that normal nutritional requirements are not met. The result is weight loss, malnutrition, and secondary anemia. Ulcers in the membranous lining of the intestine and other inflammatory changes result in a weeping, swollen intestine that continually empties an irritating discharge into the colon. Disrupted absorption causes chronic diarrhea and nutritional deficits. The result is a person who is thin and emaciated from inadequate food intake and constant fluid loss. In some patients, the inflamed intestine may perforate, leading to intra-abdominal and anal abscesses. Fever and leukocytosis occur. Chronic symptoms include diarrhea, abdominal pain, steatorrhea, anorexia, weight loss, and nutritional deficiencies.

Abscesses, fistulas, and fissures are common. Symptoms extend beyond the GI tract and commonly include joint involvement (eg, arthritis), skin lesions (eg, erythema nodosum), ocular disorders (eg, conjunctivitis), and oral ulcers. The clinical course and symptoms can vary; in some patients, periods of remission and exacerbation occur, but in others, the disease follows a fulminating course.

Assessment and Diagnostic Findings

A proctosigmoidoscopic examination is usually performed initially to determine whether the rectosigmoid area is inflamed. A stool examination is also performed; the result may be positive for occult blood and steatorrhea (ie, excessive fat in the feces). The most conclusive diagnostic aid for regional enteritis is a barium study of the upper GI tract that shows the classic “string sign” on an x-ray film of the terminal ileum, indicating the constriction of a segment of intestine. Endoscopy and intestinal biopsy may be used for confirmation of the diagnosis. A barium enema may show ulcerations (the cobblestone appearance described earlier), fissures, and fistulas. A CT scan may show bowel wall thickening and fistula tracts.

A complete blood cell count is performed to assess hematocrit and hemoglobin levels (usually decreased) and the white blood cell count (may be elevated). The sedimentation rate is usually elevated. Albumin and protein levels may be decreased, indicating malnutrition.

Complications

Complications of regional enteritis include intestinal obstruction or stricture formation, perianal disease, fluid and electrolyte imbalances, malnutrition from malabsorption, and fistula and abscess formation. A fistula is an abnormal communication between two body structures, either internal (ie, between two structures) or external (ie, between an internal structure and the outside surface of the body). The most common type of small bowel fistula that results from regional enteritis is the enterocutaneous fistula (ie, between the small bowel and the skin). Abscesses can be the result of an internal fistula tract into an area that results in fluid accumulation and infection. Patients with regional enteritis are also at increased risk for colon cancer.

ULCERATIVE COLITIS

Ulcerative colitis is a recurrent ulcerative and inflammatory disease of the mucosal and submucosal layers of the colon and rectum. The incidence of ulcerative colitis is highest in Caucasians and people of Jewish heritage (Yamada et al., 1999). The peak incidence is between 30 and 50 years of age. It is a serious disease, accompanied by systemic complications and a high mortality rate. Eventually, 10% to 15% of the patients develop carcinoma of the colon.

Pathophysiology

Ulcerative colitis affects the superficial mucosa of the colon and is characterized by multiple ulcerations, diffuse inflammations, and desquamation or shedding of the colonic epithelium. Bleeding occurs as a result of the ulcerations. The mucosa becomes edematous and inflamed. The lesions are contiguous, occurring one after the other. Abscesses form, and infiltrate is seen in the mucosa and submucosa with clumps of neutrophils in the crypt lumens (ie, crypt abscesses). The disease process usually begins in the rectum and spreads proximally to involve the entire colon. Eventually, the bowel narrows, shortens, and thickens because of muscular hypertrophy and fat deposits.

Clinical Manifestations

The clinical course is usually one of exacerbations and remissions. The predominant symptoms of ulcerative colitis are diarrhea, lower left quadrant abdominal pain, intermittent tenesmus, and rectal bleeding. The bleeding may be mild or severe, and pallor results. The patient may have anorexia, weight loss, fever, vomiting, and dehydration, as well as cramping, the feeling of an urgent need to defecate, and the passage of 10 to 20 liquid stools each day. The disease is classified as mild, severe, or fulminant, depending on the severity of the symptoms. Hypocalcemia and anemia frequently develop. Rebound tenderness may occur in the right lower quadrant. Extraintestinal symptoms include skin lesions (eg, erythema nodosum), eye lesions (eg, uveitis), joint abnormalities (eg, arthritis), and liver disease.

Assessment and Diagnostic Findings

The patient should be assessed for tachycardia, hypotension, tachypnea, fever, and pallor. Other assessments include the level of hydration and nutritional status. The abdomen should be examined for characteristics of bowel sounds, distention, and tenderness. These findings assist in determining the severity of the disease.

The stool is positive for blood, and laboratory test results reveal a low hematocrit and hemoglobin concentration in addition to an elevated white blood cell count, low albumin levels, and an electrolyte imbalance. Abdominal x-ray studies are useful for determining the cause of symptoms. Free air in the peritoneum and bowel dilatation or obstruction should be excluded as a source of the presenting symptoms. Sigmoidoscopy or colonoscopy and barium enema are valuable in distinguishing this condition from other diseases of the colon with similar symptoms. A barium enema may show mucosal irregularities, focal strictures or fistulas, shortening of the colon, and dilation of bowel loops. Endoscopy may reveal friable, inflamed mucosa with exudate and ulcerations. This procedure assists in defining the extent and severity of the disease. CT scanning, magnetic resonance imaging, and ultrasound can identify abscesses and perirectal in-

Complications

Complications of ulcerative colitis include intestinal obstruction or stricture formation, perianal disease, fluid and electrolyte imbalances, malnutrition from malabsorption, and fistula and abscess formation. A fistula is an abnormal communication between two body structures, either internal (ie, between two structures) or external (ie, between an internal structure and the outside surface of the body). The most common type of small bowel fistula that results from regional enteritis is the enterocutaneous fistula (ie, between the small bowel and the skin). Abscesses can be the result of an internal fistula tract into an area that results in fluid accumulation and infection. Patients with regional enteritis are also at increased risk for colon cancer.
volverment. Leukocyte scanning (see Chap. 34) is useful when severe colitis prohibits the use of endoscopy to determine the extent of inflammation.

**NURSING ALERT** In acute ulcerative colitis, cathartics are contraindicated when the patient is being prepared for barium enema or endoscopy because they may exacerbate the condition, which can lead to megacolon (ie, excessive dilation of the colon), perforation, and death. If the patient needs to have these diagnostic tests, a liquid diet for a few days before radiography and a gentle tap-water enema on the day of the examination may be prescribed. Colonoscopy is contraindicated in severe disease because of the risk of perforation.

Careful stool examination for parasites and other microbes is performed to rule out dysentery caused by common intestinal organisms, especially Entamoeba histolytica and Clostridium difficile.

**Complications**

Complications of ulcerative colitis include toxic megacolon, perforation, and bleeding as a result of ulceration, vascular engorge-ment, and highly vascular granulation tissue. In toxic megacolon, the inflammatory process extends into the muscularis, inhibiting its ability to contract and resulting in colonic distention. Symptoms include fever, abdominal pain and distention, vomiting, and fatigue. Colonic perforation from toxic megacolon is associated with a high mortality rate (15% to 50%) (Grendell et al., 1998). If the patient with toxic megacolon does not respond within 24 to 48 hours to medical management with nasogastric suction, intravenous fluids with electrolytes, corticosteroids, and antibiotics, surgery is required. Total colectomy is indicated. For many patients, surgery becomes necessary to relieve the effects of the disease and to treat these serious complications; an ileostomy usually is performed. The surgical procedures involved and the care of patients with this type of fecal diversion are discussed later in this chapter.

Patients with IBD also have a significantly increased risk of osteoporotic fractures due to decreased bone mineral density. Corticosteroid therapy may also contribute to the diminished bone mass.

**Medical Management of Chronic Inflammatory Bowel Disease**

Medical treatment for regional enteritis and ulcerative colitis is aimed at reducing inflammation, suppressing inappropriate immune responses, providing rest for a diseased bowel so that healing may take place, improving quality of life, and preventing or minimizing complications.

Most patients maintain long-term well-being interspersed with short intervals of illness (Hanauer, 2001). Management depends on the disease location, severity, and complications.

**NUTRITIONAL THERAPY**

Oral fluids and a low-residue, high-protein, high-calorie diet with supplemental vitamin therapy and iron replacement are prescribed to meet nutritional needs, reduce inflammation, and control pain and diarrhea. Fluid and electrolyte imbalances from dehydration caused by diarrhea are corrected by intravenous therapy as necessary if the patient is hospitalized or by oral supplementation if the patient can be managed at home. Any foods that exacerbate diarrhea are avoided. Milk may contribute to diarrhea in those with lactose intolerance. Cold foods and smoking are avoided because both increase intestinal motility. Parenteral nutrition may be indicated.

**PHARMACOLOGIC THERAPY**

Sedatives and antidiarrheal and antiperistaltic medications are used to minimize peristalsis to rest the inflamed bowel. They are continued until the patient’s stools approach normal frequency and consistency.

Aminosalicylate formulations such as sulfasalazine (Azulfidine) are often effective for mild or moderate inflammation and are used to prevent or reduce recurrences in long-term maintenance regimens. Newer sulfa-free aminosalicylates (eg, mesalamine [Asacol, Pentasa]) have been developed and shown effective in preventing and treating recurrence of inflammation (Wolfe, 2000). Antibiotics are used for secondary infections, particularly for purulent complications such as abscesses, perforation, and peritonitis.

Corticosteroids are used to treat severe and fulminant disease. These corticosteroids (eg, prednisone) can be administered orally in outpatient treatment or parenterally in hospitalized patients. Topical (ie, rectal administration) corticosteroids are also widely used in the treatment of distal colon disease. When the dosage of corticosteroids is reduced or stopped, the symptoms of disease may return. If corticosteroids are continued, adverse sequela such as hypertension, fluid retention, cataracts, hirsutism (ie, abnormal hair growth), adrenal suppression, and loss of bone density may develop.

Immunomodulators (eg, azathioprine [Imuran], 6-mercaptopurine, methotrexate, cyclosporin) have been used to alter the immune response (Wolfe, 2000). The exact mechanism of action of these medications in treating IBD is unknown. They are used for patients with severe disease who have failed other therapies. These medications are useful in maintenance regimens to prevent relapses. Newer biologic therapies are being studied, and it is hoped that they will lead to improvement in the treatment of patients with chronically active disease (Yamada et al., 1999).

**SURGICAL MANAGEMENT**

When nonsurgical measures fail to relieve the severe symptoms of IBD, surgery may be recommended. The most common indications for surgery are medically intractable disease, poor quality of life, or complications from the disease or medical therapy (Wolfe, 2000).

More than one half of all patients with regional enteritis require surgery at some point. Recurrence of inflammation and disease after surgery in regional enteritis is inevitable. The rate of recurrence after surgery is 20% to 40% in the first 5 years. Patients younger than 25 years of age have the highest recurrence rate. Surgery for regional enteritis is indicated for refractory disease or complications (Wolfe, 2000). The procedure of choice is a total colectomy and ileostomy.

A newer surgical procedure developed for patients with severe regional enteritis is intestinal transplant. This technique is now available to children and to young and middle-age adults who have lost intestinal function from disease. Although not a cure, this procedure may eventually provide improvement in quality of life for some who are terminally ill. The technical and immunologic problems with this procedure remain formidable, and the costs and mortality rates remain high (Wolfe, 2000).

Approximately 15% to 20% of patients with ulcerative colitis require surgical intervention (Tierney et al., 2000). Indications for surgery include lack of improvement and continued deterioration, profuse bleeding, perforation, stricture formation, and cancer. Surgical excision usually improves quality of life.
Proctocolectomy with ileostomy (ie, complete excision of colon, rectum, and anus) is recommended when the rectum is severely involved.

One type of surgical technique that can be helpful is strictureplasty, in which the blocked or narrowed section of the bowel is widened, leaving the bowel intact. If a lesion can be delineated in regional enteritis or if a complication has occurred, the lesion is resected, and the remaining portions of the bowel are Anastomosed. Surgical removal of up to 50% of the small bowel usually can be tolerated. Other types of surgical procedures, known as fecal diversions, are discussed later in this chapter.

**Total Colectomy With Ileostomy.** An ileostomy, the surgical creation of an opening into the ileum or small intestine (usually by means of an ileal stoma on the abdominal wall), is commonly performed after a total colectomy (ie, excision of the entire colon). It allows for drainage of fecal matter (ie, effluent) from the ileum to the outside of the body. The drainage is very mushy and occurs at frequent intervals. Nursing management of the patient with an ileostomy is discussed in a later section of this chapter.

**Total Colectomy With Continent Ileostomy.** Another procedure involves the removal of the entire colon and creation of the continent ileal reservoir (ie, Kock pouch). This procedure eliminates the need for an external fecal collection bag. Approximately 30 cm of the distal ileum is reconstructed to form a reservoir with a nipple valve that is created by pulling a portion of the terminal ileal loop back into the ileum. GI effluent can accumulate in the pouch for several hours and then be removed by means of a catheter inserted through the nipple valve. The major problem with the Kock pouch is malfunction of the nipple valve, which occurs in about 20% of the patients (Yamada et al., 1999).

**Total Colectomy With Ileoanal Anastomosis.** A total colectomy with ileoanal anastomosis is another surgical procedure that eliminates the need for a permanent ileostomy. It establishes an ileal reservoir, and anal sphincter control of elimination is retained. The procedure involves connecting a portion of the ileum to the anus (ie, ileoanal anastomosis) in conjunction with removal of the colon and the rectal mucosa (ie, total abdominal colectomy and mucosal proctectomy) (Fig. 38-5). A temporary diverting loop ileostomy is constructed at the time of surgery and closed about 3 months later.

With ileoanal anastomosis, the diseased colon and rectum are removed, voluntary defection is maintained, and anal continence is preserved. The ileal reservoir decreases the number of bowel movements by 50%, from approximately 14 to 20 per day to 7 to 10 per day. Nighttime elimination is gradually reduced to one bowel movement. Complications of ileoanal anastomosis include irritation of the perianal skin from leakage of fecal contents, stricture formation at the anastomosis site, and small bowel obstruction.

**Nursing Management**

Nursing management of patients with IBD may be medical, surgical, or both. Patients in the community setting or those recently diagnosed may primarily require education about diet and medications and referral to support groups. Hospitalized patients with long-standing or severe disease also require careful monitoring, parenteral nutrition, fluid replacement, and possibly emergent surgery. The surgical procedures may involve a fecal diversion, with attendant needs for physical care, emotional support, and extensive teaching about management of the ostomy.

**NURSING PROCESS:**

**MANAGEMENT OF THE PATIENT WITH INFLAMMATORY BOWEL DISEASE**

**Assessment**

The nurse takes a health history to identify the onset, duration, and characteristics of abdominal pain; the presence of diarrhea or fecal urgency, straining at stool (tenesmus), nausea, anorexia, or weight loss; and family history of IBD. It is important to discuss dietary patterns, including the amounts of alcohol, caffeine, and nicotine containing products used daily and weekly. The nurse asks about patterns of bowel elimination, including character, frequency, and presence of blood, pus, fat, or mucus. It is important to note allergies and food intolerance, especially milk (lactose) intolerance. The patient may identify sleep disturbances if diarrhea or pain occurs at night.

Assessment includes auscultating the abdomen for bowel sounds and their characteristics; palpating the abdomen for distention, tenderness, or pain; and inspecting the skin for evidence of fistula tracts or symptoms of dehydration. The stool is inspected for blood and mucus.

With regional enteritis, pain is usually localized in the right lower quadrant, where hyperactive bowel sounds can be heard because of borborygmus and increased peristalsis. Abdominal tenderness is noticed on palpation. The most prominent symptom is intermittent pain that occurs with diarrhea but does not decrease after defection. Pain in the periumbilical region usually indicates involvement of the terminal ileum. With ulcerative col-
itis, the abdomen may be distended, and rebound tenderness may be present. Rectal bleeding is a significant sign.

**Diagnosis**

**NURSING DIAGNOSES**

Based on the assessment data, the nursing diagnoses may include the following:

- Diarrhea related to the inflammatory process
- Acute pain related to increased peristalsis and GI inflammation
- Deficient fluid volume deficit related to anorexia, nausea, and diarrhea
- Imbalanced nutrition, less than body requirements, related to dietary restrictions, nausea, and malabsorption
- Activity intolerance related to fatigue
- Anxiety related to impending surgery
- Ineffective coping related to repeated episodes of diarrhea
- Risk for impaired skin integrity related to malnutrition and diarrhea
- Risk for ineffective therapeutic regimen management related to insufficient knowledge concerning the process and management of the disease

**COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS**

Potential complications that may develop include the following:

- Electrolyte imbalance
- Cardiac dysrhythmia related to electrolyte depletion
- GI bleeding with fluid volume loss
- Perforation of the bowel

**Planning and Goals**

The major goals for the patient include attainment of normal bowel elimination patterns, relief of abdominal pain and cramping, prevention of fluid volume deficit, maintenance of optimal nutrition and weight, avoidance of fatigue, reducing anxiety, promoting effective coping, absence of skin breakdown, learning about the disease process and therapeutic regimen, and avoidance of complications.

**Nursing Interventions**

**MAINTAINING NORMAL ELIMINATION PATTERNS**

The nurse determines if there is a relationship between diarrhea and certain foods, activity, or emotional stress. Identifying precipitating factors, the frequency of bowel movements, and the character, consistency, and amount of stool passed is important. The nurse provides ready access to a bathroom, commode, or bedpan and keeps the environment clean and odor free. It is important to administer antidiarrheal medications as prescribed, to record the frequency and consistency of stools after therapy is initiated, and to encourage bed rest to decrease peristalsis.

**RELIEVING PAIN**

The character of the pain is described as dull, burning, or crampy. Asking about its onset is relevant. Does it occur before or after meals, during the night, or before elimination? Is the pattern constant or intermittent? Is it relieved with medications? The nurse administers anticholinergic medications as prescribed 30 minutes before a meal to decrease intestinal motility and administers analgesics as prescribed for pain. Position changes, local application of heat (as prescribed), diversional activities, and the prevention of fatigue also are helpful for reducing pain.

**MAINTAINING FLUID INTAKE**

To detect fluid volume deficit, the nurse keeps an accurate record of oral and intravenous fluids and maintains a record of output (ie, urine, liquid stool, vomitus, and wound or fistula drainage). The nurse monitors daily weights for fluid gains or losses and assesses the patient for signs of fluid volume deficit (ie, dry skin and mucous membranes, decreased skin turgor, oliguria, exhaustion, decreased temperature, increased hematocrit, elevated urine specific gravity, and hypotension). It is important to encourage oral intake of fluids and to monitor the intravenous flow rate. The nurse initiates measures to decrease diarrhea (eg, dietary restrictions, stress reduction, antidiarrheal agents).

**MAINTAINING OPTIMAL NUTRITION**

Parenteral nutrition (PN) is used when the symptoms of IBD are severe. With PN, the nurse maintains an accurate record of fluid intake and output as well as the patient’s daily weight. The patient should gain 0.5 kg daily during PN therapy. Because PN is very high in glucose and can cause hyperglycemia, blood glucose levels are monitored every 6 hours. Elemental feedings high in protein and low in fat and residue are instituted after PN therapy because they are digested primarily in the jejunum, do not stimulate intestinal secretions, and allow the bowel to rest. The nurse notes intolerance if the patient exhibits nausea, vomiting, diarrhea, or abdominal distention.

If oral foods are tolerated, small, frequent, low-residue feedings are given to avoid overdistending the stomach and stimulating peristalsis. It is important for the patient to restrict activity to conserve energy, reduce peristalsis, and reduce calorie requirements.

**PROMOTING REST**

The nurse recommends intermittent rest periods during the day and schedules or restricts activities to conserve energy and reduce the metabolic rate. It is important to encourage activity within the limits of the patient’s capacity. The nurse suggests bed rest for a patient who is febrile, has frequent diarrheal stools, or is bleeding. The patient on bed rest should perform active exercises to maintain muscle tone and prevent thromboembolic complications. If the patient is unable to perform these active exercises, the nurse performs passive exercises and joint range of motion. Activity restrictions are modified as needed on a day-to-day basis.

**REDUCING ANXIETY**

Rapport can be established by being attentive and displaying a calm, confident manner. The nurse allows time for the patient to ask questions and express feelings. Careful listening and sensitivity to nonverbal indicators of anxiety (eg, restlessness, tense facial expressions) are helpful. The patient may be emotionally labile because of the consequences of the disease; the nurse tailors information about possible impending surgery to the patient’s level of understanding and desire for detail. If surgery is planned, pictures and illustrations help to explain the surgical procedure and help the patient to visualize what a stoma looks like.
ENHANCING COPING MEASURES
Because the patient may feel isolated, helpless, and out of control, understanding and emotional support are essential. The patient may respond to stress in a variety of ways that may alienate others, including anger, denial, and social self-isolation.

The nurse needs to recognize that the patient’s behavior may be affected by a number of factors unrelated to inherent emotional characteristics. Any patient suffering the discomforts of frequent bowel movements and rectal soreness is anxious, discouraged, and depressed. It is important to develop a relationship with the patient that supports all attempts to cope with these stresses. It is also important to communicate that the patient’s feelings are understood by encouraging the patient to talk and express his or her feelings and to discuss any concerns. Stress reduction measures that may be used include relaxation techniques, visualization, breathing exercises, and biofeedback. Professional counseling may be needed to help the patient and family manage issues associated with chronic illness.

PREVENTING SKIN BREAKDOWN
The nurse examines the patient’s skin frequently, especially the perianal skin. Perianal care, including the use of a skin barrier, is important after each bowel movement. The nurse gives immediate attention to reddened or irritated areas over a bony prominence and uses pressure-relieving devices to prevent skin breakdown. Consultation with a wound care specialist or enterostomal therapist is often helpful.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS
Serum electrolyte levels are monitored daily, and electrolyte replacements are administered as prescribed. It is important to report evidence of dysrhythmias or change in level of consciousness immediately.

The nurse closely monitors rectal bleeding and administers blood component therapy and volume expanders as prescribed to prevent hypovolemia. It is important to monitor the blood pressure for hypotension and to obtain coagulation and hematocrit and hemoglobin profiles frequently. Vitamin K may be prescribed to increase clotting factors.

The nurse closely monitors the patient for indications of perforation (ie, acute increase in abdominal pain, rigid abdomen, vomiting, or hypotension) and obstruction and toxic megacolon (ie, abdominal distention, decreased or absent bowel sounds, change in mental status, fever, tachycardia, hypotension, dehydration, and electrolyte imbalances).

PROMOTING HOME AND COMMUNITY-BASED CARE
Teaching Patients Self-Care
The nurse assesses the patient’s understanding of the disease process and his or her need for additional information about medical management (eg, medications, diet) and surgical interventions. The nurse provides information about nutritional management; a bland, low-residue, high-protein, high-calorie, and high-vitamin diet relieves symptoms and decreases diarrhea. It is important to provide the rationale for the use of corticosteroids and anti-inflammatory, antibacterial, antidiarrheal, and antispasmodic medications. The nurse emphasizes the importance of taking medications as prescribed and not abruptly discontinuing them (especially corticosteroids) to avoid development of serious medical problems (Chart 38-3). The nurse reviews ileostomy care as necessary (see Nursing Management of the Patient with an Ileostomy). Patient education information can be obtained from the National Foundation for Ileitis and Colitis.

Continuing Care
Patients with chronic inflammatory disease are managed at home with follow-up care by their physician or through an outpatient clinic. Those whose nutritional status is compromised and who are receiving PN need home care nursing to ensure that their nutritional requirements are being met and that they or their caregivers can follow through with the instructions for PN. Patients who are medically managed need to understand that their disease can be controlled and that they can lead a healthy life between exacerbations. Control implies management based on an understanding of the disease and its treatment. Patients in the home setting need information about their medications (ie, name, dose, side effects, and frequency of administration) and need to take medications on schedule. Medication reminders such as containers that separate pills according to day and time or daily checklists are helpful.

During a flare-up, the nurse encourages patients to rest as needed and to modify activities according to their energy levels. Patients should limit tasks that impose strain on the lower abdominal muscles. They should sleep in a room close to the bathroom because of the frequent diarrhea (10 to 20 times per day); quick access to a toilet helps alleviate the worry of embarrassment if an accident occurs. Room deodorizers help control odors.

Dietary modifications can control but not cure the disease; the nurse recommends a low-residue, high-protein, high-calorie diet, especially during an acute phase. It is important to encourage patients to keep a record of the foods that irritate the bowel and to eliminate them from the diet and to remind patients to drink at least eight glasses of water each day.

The prolonged nature of the disease has an impact on the patient and often strains his or her family life and financial resources as well. Family support is vital; however, some family members may be resentful, guilty, and tired and feel unable to continue coping with the emotional demands of the illness and the physical demands of caring for another. Some patients with IBD do not socialize for fear of being embarrassed. Many prefer to eat alone. Because they have lost control over elimination, they may fear losing control over other aspects of their lives. They need time to express their fears and frustrations. Individual and family counseling may be helpful.

**Evaluation**

**EXPECTED PATIENT OUTCOMES**

Expected patient outcomes may include the following:

1. Reports a decrease in the frequency of diarrhea stools
   - a. Complies with dietary restrictions; maintains bed rest
   - b. Takes medications as prescribed
2. Has reduced pain
3. Maintains fluid volume balance
   - a. Drinks 1 to 2 L of oral fluids daily
   - b. Has a normal body temperature
   - c. Displays adequate skin turgor and moist mucous membranes
4. Attains optimal nutrition; tolerates small, frequent feedings without diarrhea
5. Avoids fatigue
   - a. Rests periodically during the day
   - b. Adheres to activity restrictions
6. Is less anxious
7. Copes successfully with diagnosis
   - a. Expresses feelings freely
   - b. Uses appropriate stress reduction behaviors
8. Maintains skin integrity
   - a. Cleans perianal skin after defecation
   - b. Uses lotion or ointment as skin barrier
9. Acquires an understanding of the disease process
   - a. Modifies diet appropriately to decrease diarrhea
   - b. Adheres to medication regimen
10. Recovers without complications
    - a. Maintains electrolytes within normal ranges
    - b. Maintains normal sinus or baseline cardiac rhythm
    - c. Maintains fluid balance
    - d. Experiences no perforation or rectal bleeding

**NURSING MANAGEMENT OF THE PATIENT REQUIRING AN ILEOSTOMY**

Some patients with IBD eventually require permanent fecal diversion with creation of an ileostomy to manage symptoms and to treat or prevent complications. The Plan of Nursing Care 38-1 summarizes care for the patient requiring an ostomy.

**Providing Preoperative Care**

A period of preparation with intensive replacement of fluid, blood, and protein is necessary before surgery is performed. Antibiotics may be prescribed. If the patient has been taking corticosteroids, they will be continued during the surgical phase to prevent steroid-induced adrenal insufficiency. Usually, the patient is given a low-residue diet, provided in frequent, small feedings. All other preoperative measures are similar to those for general abdominal surgery. The abdomen is marked for the proper placement of the stoma by the surgeon or the enterostomal therapist. Care is taken to ensure that the ostomy stoma is conveniently placed—usually in the right lower quadrant about 2 inches below the waist, in an area away from previous scars, bony prominence, skin folds, or fistulas.

The patient must have a thorough understanding of the surgery to be performed and what to expect after surgery. Information about an ileostomy is presented to the patient by means of written materials, models, and discussion. Preoperative teaching includes management of drainage from the stoma, the nature of drainage, and the need for nasogastric intubation, parenteral fluids, and possibly perineal packing.

**Providing Postoperative Care**

General abdominal surgery wound care is required. The nurse observes the stoma for color and size. It should be pink to bright red and shiny. For the traditional ileostomy, a temporary plastic bag with adhesive facing is placed over the ileostomy and firmly pressed onto surrounding skin. The nurse monitors the ileostomy for fecal drainage, which should begin about 72 hours after surgery. The drainage is a continuous liquid from the small intestine because the stoma does not have a controlling sphincter. The contents drain into the plastic bag and are thus kept from coming into contact with the skin. They are collected and measured when the bag becomes full. If a continent ileal reservoir was created, as described for the Kock pouch, continuous drainage is provided by an indwelling reservoir catheter for 2 to 3 weeks after surgery. This allows the suture lines to heal.

As with other patients undergoing abdominal surgery, the nurse encourages those with an ileostomy to engage in early ambulation. It is important to administer prescribed pain medications as required.

Because these patients lose much fluid in the early postoperative period, an accurate record of fluid intake, urinary output, and fecal discharge is necessary to help gauge the fluid needs of the patient. There may be 1000 to 2000 mL of fluid lost each day in addition to expected fluid loss through urine, perspiration, respiration, and other sources. With this loss, sodium and potassium are depleted. The nurse monitors laboratory values and administers electrolyte replacements as prescribed. Intravenous fluids are administered to replace fluid losses for 4 to 5 days.

Nasogastric suction is also a part of immediate postoperative care, with the tube requiring frequent irrigation, as prescribed. The purpose of nasogastric suction is to prevent a buildup of gastric contents. After the tube is removed, the nurse offers sips of clear liquids and gradually progresses the diet. It is important to immediately report nausea and abdominal distention, which may indicate obstruction.

By the end of the first week, rectal packing is removed. Because this procedure may be uncomfortable, the nurse may administer an analgesic an hour before it is performed. After the packing is removed, the perineum is irrigated two or three times daily until full healing takes place.

**PROVIDING EMOTIONAL SUPPORT**

The patient understandably may think that everyone is aware of the ileostomy and may view the stoma as a mutilation compared with other abdominal incisions that heal and are hidden. Because
### Plan of Nursing Care

**The Patient Undergoing Ostomy Surgery**

<table>
<thead>
<tr>
<th>Nursing Interventions</th>
<th>Rationale</th>
<th>Expected Outcomes</th>
</tr>
</thead>
</table>
| **Nursing Diagnosis:** Deficient knowledge about the surgical procedure and preoperative preparation  
**Goal:** Understands the surgical process and the necessary preoperative preparations | 1. Fear of a repeated negative experience increases anxiety. Talking about the experience with a nurse helps clarify misconceptions and helps the patient ventilate any repressed emotions. Positive experiences are reinforced.  
2. Clarification prevents misunderstandings and alleviates anxiety. A positive affect may be more difficult to project if the ostomy is permanent or the prognosis poor. | • Expresses anxieties and fears about the surgical process  
• Projects a positive attitude toward the surgical procedure  
• Repeats in own words information given by the surgeon  
• Identifies normal anatomy and physiology of gastrointestinal tract and how it will be altered; can point to expected location of abdominal wound and stoma; describes stoma appearance and size  
• Adheres to “bowel prep” regimen of antimicrobials or mechanical cleansing  
• Tolerates the presence of nasogastric/nasoenteric tube |

#### Preoperative Care

1. Ascertain whether the patient has had a previous surgical experience and ask for recollections of positive and negative impressions.  
2. Determine what information the surgeon gave the patient and family and whether it was understood. Clarify and elaborate as necessary. Determine whether the stoma is permanent or temporary. Be aware of the patient’s prognosis if carcinoma exists.  
3. Use pictures or drawings to illustrate the location and appearance of the surgical wounds (abdominal, perineal) and the stoma if the patient is receptive.  
4. Explain that oral/parenteral antimicrobials will be administered to cleanse the bowel preoperatively. Mechanical cleansing may also be required.  
5. Assist the patient during nasogastric/nasoenteric intubation. Measure drainage from the tube.

| Nursing Diagnosis: Disturbed body image  
**Goal:** Attainment of a positive self-concept | 1. Free expression of feelings allows the patient the opportunity to verbalize and identify concerns. Expressed concerns can be therapeutically addressed by health care team members.  
2. Helps patient to overcome fears about partner’s response.  
3. Provides opportunity for additional support.  
4. Ostomates can offer support and share mutual feelings and experiences. | • Freely expresses concerns  
• Accepts support  
• Seeks help as needed  
• States is willing to talk with an ostomate |

1. Encourage the patient to verbalize feelings about the stoma. Offer to be present when the stoma is first viewed and touched.  
2. Suggest that the spouse or significant other view the stoma.  
3. Offer counseling, if desired.  
4. Arrange for a visit with an ostomate.

| Nursing Diagnosis: Anxiety related to the loss of bowel control  
**Goal:** Reduction of anxiety | 1. Emotional adjustment is facilitated if adequate information is provided at the level of the learner.  
2. Adequate fit is necessary for successful use of the appliance. | • Expresses interest in learning about altered bowel function  
• Handles equipment correctly  
• Changes the appliance unassisted  
• Irrigates colostomy successfully  
• Progresses toward a regular schedule of elimination |

1. Provide information about expected bowel function:  
   a. Characteristics of effluent  
   b. Frequency of discharge  
2. Teach the patient how to prepare the appliance for an adequate fit.
### Plan of Nursing Care

#### Nursing Diagnosis: Risk for impaired skin integrity related to irritation of the peristomal skin by the effluent

**Goal:** Maintenance of skin integrity

1. Provide information about signs and symptoms of irritated or inflamed skin. Use pictures if possible.
2. Teach patient how to cleanse the peristomal skin gently.
3. Demonstrate how to apply a skin barrier (powder, gel, paste, wafer).
4. Demonstrate how to remove the pouch.

| 1. Peristomal skin should be slightly pink without abrasions and similar to that of the entire abdomen. | • Describes appearance of healthy skin  
• Correctly cleanses the skin  
• Successfully applies a skin barrier  
• Gently removes the drainage appliance without skin damage  
• Demonstrates intact skin around the colostomy stoma |
| 2. Mild friction with warm water and a gentle soap cleanses the skin and minimizes irritation and possible abrasions. Parting the skin dry prevents tissue trauma. |  |
| 3. Skin barriers protect the peristomal skin from enzymes and bacteria. |  |
| 4. Gently separate adhesive from the skin to avoid irritation. Never pull! |  |

#### Nursing Diagnosis: Potential imbalanced nutrition, less than body requirements, related to avoidance of foods that may cause GI discomfort

**Goal:** Achievement of an optimal nutritional intake

1. Conduct a complete nutritional assessment to identify any foods that may increase peristalsis by irritating the bowel.
2. Advise the patient to avoid food products with a cellulose or hemicellulose base (nuts, seeds).
3. Recommend moderation in intake of certain irritating fruits such as prunes, grapes, and bananas.

| 1. Patients react differently to certain foods because of individual sensitivity. | • Modifies diet to avoid offensive foods yet maintains adequate nutritional intake  
• Avoids foods such as peanuts  
• Modifies intake of certain fruits |
| 2. Cellulose food products are the non-digestible residue of plant foods. They hold water, provide bulk, and stimulate elimination. |  |
| 3. These fruits tend to increase the quantity of effluent. |  |

(continued)
there is loss of a body part and a major change in anatomy, the patient often goes through the various phases of grieving—shock, disbelief, denial, rejection, anger, and restitution. Nursing support through these phases is important, and understanding of the patient’s emotional outlook in each instance should determine the approach taken. For example, teaching may be ineffective until the patient is ready to learn. Concern about body image may lead to questions related to family relationships, sexual function, and for women, the ability to become pregnant and to deliver a baby normally. Patients need to know that someone understands and cares about them. A calm, nonjudgmental attitude exhibited by the nurse aids in gaining the patient’s confidence. It is important to recognize the dependency needs of these patients. Their prolonged illness can make them irritable, anxious, and de-
pressed. The nurse can coordinate patient care through meetings attended by consultants such as the physician, psychologist, psychiatrist, social worker, enterostomal therapist, and dietitian. The team approach is important in facilitating the often complex care of this patient.

Conversely, a surgical procedure to create an ileostomy can produce dramatic positive changes in patients who have suffered from IBD for several years. After the continuous discomfort of the disease has decreased and patients learn how to take care of the ileostomy, they often develop a more positive outlook. Until they progress to this phase, an empathetic and tolerant approach by the nurse plays an important part in recovery. The sooner the patient masters the physical care of the ileostomy, the sooner he or she will psychologically accept it.

The support of other ostomates is also helpful. The United Ostomy Association is dedicated to the rehabilitation of ostomates. This organization gives patients useful information about living with an ostomy through an educational program of literature, lectures, and exhibits. Local associations offer visiting services by qualified members who provide hope and rehabilitation services to new ostomy patients. Hospitals and other health care agencies may have an enterostomal therapy nurse on staff who can serve as a valuable resource person for the ileostomy patient.

MANAGING SKIN AND STOMA CARE
The patient with a traditional ileostomy cannot establish regular bowel habits because the contents of the ileum are fluid and are discharged continuously. The patient must wear a pouch at all times. Stomal size and pouch size vary initially; the stoma should be rechecked 3 weeks after surgery, when the edema has subsided. The final size and type of appliance is selected in 3 months, after the patient’s weight has stabilized, and the stoma shrinks to a stable shape.

The location and length of the stoma are significant in the management of the ileostomy by the patient. The surgeon positions the stoma as close to the midline as possible and at a location where even an obese patient with a protruding abdomen can care for it easily. Usually, the ileostomy stoma is about 2.5 cm (1 in) long, which makes it convenient for the attachment of an appliance.

Skin excoration around the stoma can be a persistent problem. Peristomal skin integrity may be compromised by several factors, such as an allergic reaction to the ostomy appliance, skin barrier, or paste; chemical irritation from the effluent; mechanical injury from the removal of the appliance; and possible infection. If irritation and yeast growth occur, nystatin powder (Mycostatin) is dusted lightly on the peristomal skin.

CHANGING AN APPLIANCE
A regular schedule for changing the pouch before leakage occurs must be established for those with a traditional ileostomy. The patient can be taught to change the pouch in a manner similar to that described in Chart 38-4.

The amount of time a person can keep the appliance sealed to the body surface depends on the location of the stoma and on body structure. The usual wearing time is 5 to 7 days. The appliance is emptied every 4 to 6 hours or at the same time the patient empties the bladder. An emptying spout at the bottom of the appliance is closed with a special clip made for this purpose.

Most pouches are disposable and odor-proof. Foods such as spinach and parsley act as deodorizers in the intestinal tract; foods that cause odors include cabbage, onions, and fish. Bismuth subcarbonate tablets, which may be prescribed and taken by mouth three or four times each day, are effective in reducing odor. A stool thickener, such as diphenoxylate (Lomotil), can also be prescribed and taken orally to assist in odor control.

IRRIGATING A CONTINENT ILEOSTOMY
For a continent ileostomy (ie, Kock pouch), the nurse teaches the patient to drain the pouch, as described in Chart 38-5. A catheter is inserted into the reservoir to drain the fluid. The length of time between drainage periods is gradually increased until the reservoir needs to be drained only every 4 to 6 hours and irrigated once each day. A pouch is not necessary; instead, most patients wear a small dressing over the opening.

When the fecal discharge is thick, water can be injected through the catheter to loosen and soften it. The consistency of the effluent is affected by food intake. At first, drainage is only 60 to 80 mL, but as time goes on, the amount increases significantly. The internal Kock pouch stretches, eventually accommodating 500 to 1000 mL. The patient learns to use the sensation of pressure in the pouch as a gauge to determine how often the pouch should be drained.

MANAGING DIETARY AND FLUID NEEDS
A low-residue diet is followed for the first 6 to 8 weeks. Strained fruits and vegetables are given. These foods are important sources of vitamins A and C. Later, there are few dietary restrictions, except for avoiding foods that are high in fiber or hard-to-digest kernels, such as celery, popcorn, corn, poppy seeds, caraway seeds, and coconut. Foods are reintroduced one at a time. The nurse assesses the patient’s tolerance for these foods and reminds him or her to chew food thoroughly.

Fluids may be a problem during the summer, when fluid lost through perspiration adds to the fluid loss through the ileostomy. Fluids such as Gatorade are helpful in maintaining the electrolyte balance. If the fecal discharge is too watery, fibrous foods (eg, whole-grain cereals, fresh fruit skins, beans, corn, nuts) are restricted. If the effluent is excessively dry, salt intake is increased. Increased intake of water or fluid does not increase the effluent, because excess water is excreted in the urine.

PREVENTING COMPLICATIONS
Monitoring for complications is an ongoing activity for the patient with an ileostomy. Minor complications occur in about 40% of patients who have an ileostomy; less than 20% of the complications require surgical intervention (Kirsner & Shorter, 2000).

Common complications include skin irritation, diarrhea, stomal stenosis, urinary calculi, and cholelithiasis. Peristomal skin irritation, the most common complication of an ileostomy, results from leakage of effluent. A pouch that does not fit well is often the cause. The nurse or an enterostomal therapist adjusts the pouch and skin barriers are applied. Diarrhea, manifested by very irritating effluent that rapidly fills the pouch (every hour or sooner), can quickly lead to dehydration and electrolyte losses. Supplemental water, sodium, and potassium are administered to prevent hypovolemia and hypokalemia. Antidiarrheal agents are administered. Stenosis is caused by circular scar tissue that forms at the stoma site. The scar tissue must be surgically released. Urinary calculi occur in about 10% of ileostomy patients because of dehydration from decreased fluid intake. Intense lower abdominal pain that radiates to the legs, hematuria, and signs of dehydration indicate that the urine should be strained. Fluid intake is encouraged. Sometimes, small stones are passed during urination; otherwise, treatment is necessary to crush or remove the calculi (see Chap. 45).

Cholelithiasis (ie, gallstones) occurs three times more commonly in patients with an ileostomy than in the general population.
Chart 38-4
GUIDELINES FOR Changing an Ostomy Appliance

Changing an ileostomy appliance is necessary to prevent leakage (the bag is usually changed every 5 to 7 days), to allow for examination of the skin around the stoma, and to assist in controlling odor if this becomes a problem. The appliance should be changed at any time that the patient complains of burning or itching under the disk or pain in the area of the stoma; routine changes should be performed early in the morning before breakfast or 2 to 4 hours after a meal, when the bowel is least active.

(continued)
Chapter 38  Management of Patients With Intestinal and Rectal Disorders

NURSING ACTION RATIONALE

3. Cleanse the skin:
   a. Wash the skin gently with a soft cloth moistened with tepid water and mild soap; the patient may prefer to bathe before putting on a clean appliance.
   b. Rinse and dry the skin thoroughly after cleansing.

4. Apply appliance (when there is no skin irritation):
   a. An appropriate skin barrier is applied to the peristomal skin before the appliance is applied.
   b. Remove cover from adherent surface of disk of disposable plastic appliance and apply directly to the skin.
   c. Press firmly in place for 30 s to ensure adherence.

5. Apply appliance (when there is skin irritation):
   a. Cleanse the skin thoroughly but gently; pat dry.
   b. Apply Kenalog spray; blot excess moisture with a cotton pledget and dust lightly with nystatin (Mycostatin) powder.

   OR

   Apply as an alternative a wafer of Stomahesive (Squibb), which is commercially available. The stomal opening should be cut the same size as the stoma; use a cutting guide (supplied with Stomahesive). The wafer is applied directly to the skin.
   c. Another alternative is to moisten a karaya gum washer and apply when it is tacky. If the skin is moist, karaya powder may be applied first and any excess dusted off gently.
   d. The pouch is then applied to the treated skin.

6. Check the pouch bottom for closure; use the rubber band or clip provided.

3. The patient may shower with or without the pouch.
   a. Micropore or waterproof tape applied to the sides of the face-plate will keep it secure during bathing.
   b. Moisture or soap residue will interfere with appliance adhesion.

4. Many appliances have a built-in skin barrier. The skin should be thoroughly dried before applying the appliance.

Chart 38-4

5. Apply appliance (when there is skin irritation):
   a. To remove debris.
   b. The corticosteroid preparation (Kenalog) helps to decrease inflammation. The antifungal agent (nystatin) treats those types of infections that are common around stomas. A prescription is required for either medication.

   OR

   Apply as an alternative a wafer of Stomahesive (Squibb), which is commercially available. The stomal opening should be cut the same size as the stoma; use a cutting guide (supplied with Stomahesive). The wafer is applied directly to the skin.
   c. Karaya also facilitates skin healing. Tackiness promotes adherence.
   d. This will allow skin to heal while the appliance is in place.

6. Proper closure controls leakage.

because of changes in the absorption of bile acids that occur postoperatively. Spasm of the gallbladder causes severe upper right abdominal pain that can radiate to the back and right shoulder (see Chap. 40).

PROMOTING HOME AND COMMUNITY-BASED CARE

Teaching Patients Self-Care

The spouse and family should be familiar with the adjustment that will be necessary when the patient returns home. They need to know why it is necessary for the patient to occupy the bathroom for 10 minutes or more at certain times of the day and why certain equipment is needed. Their understanding is necessary to reduce tension; a relaxed patient tends to have fewer problems. Visits from an enterostomal therapy nurse may be arranged to ensure that the patient is progressing as expected and to provide additional guidance and teaching as needed.

The patient needs to know the commercial name of the pouch to be used so that he or she can obtain a ready supply and should have information about obtaining other supplies. The names and contact information of the local enterostomal therapy nurse and local self-help groups are often helpful. Any special restrictions on driving or working also need to be reviewed. The nurse teaches the patient about common postoperative complications and how to recognize and report them (Chart 38-6).
Intestinal Obstruction

Intestinal obstruction exists when blockage prevents the normal flow of intestinal contents through the intestinal tract. Two types of processes can impede this flow.

- **Mechanical obstruction:** An intraluminal obstruction or a mural obstruction from pressure on the intestinal walls occurs. Examples are intussusception, polyoid tumors and neoplasms, stenosis, strictures, adhesions, hernias, and abscesses.

- **Functional obstruction:** The intestinal musculature cannot propel the contents along the bowel. Examples are amyloidosis, muscular dystrophy, endocrine disorders such as diabetes mellitus, or neurologic disorders such as Parkinson’s disease. The blockage also can be temporary and the result of the manipulation of the bowel during surgery.

The obstruction can be partial or complete. Its severity depends on the region of bowel affected, the degree to which the lumen is occluded, and especially the degree to which the vascular supply to the bowel wall is disturbed.

Most bowel obstructions occur in the small intestine. Adhesions are the most common cause of small bowel obstruction, followed by hernias and neoplasms. Other causes include intussusception, volvulus (ie, twisting of the bowel), and paralytic ileus. About 15% of intestinal obstructions occur in the large bowel; most of these are found in the sigmoid colon (Wolfe, 2000). The most common causes are carcinoma, diverticulitis, inflammatory bowel disorders, and benign tumors. Table 38-5 and Figure 38-6 list mechanical causes of obstruction and describe how they occur.

---

**Chart 38-5**

**GUIDELINES FOR Draining a Continent Ileostomy (Kock Pouch)**

A continent ileostomy is the surgical creation of a pouch of small intestine that can serve as an internal receptacle for fecal discharge; a nipple valve is constructed at the outlet. Postoperatively, a catheter extends from the stoma and is attached to a closed drainage suction system. To ensure patency of the catheter, usually every 3 hours 10 to 20 mL of normal saline is instilled gently into the pouch; return flow is not aspirated but is allowed to drain by gravity.

After approximately 2 weeks, when the healing process has progressed to the point at which the catheter is removed from the stoma, the patient is taught to drain the pouch. The equipment required includes a catheter, tissues, water-soluble lubricant, gauze squares, a syringe, irrigating solution in a bowl, and an emesis or receiving basin.

The following procedure is used to drain the pouch; the patient is helped to participate in this procedure to learn to perform it unassisted.

**NURSING ACTION**

1. Lubricate the catheter and gently insert it about 5 cm (2 in), at which point some resistance may be felt at the valve or nipple.
2. If there is much resistance, fill a syringe with 20 mL of air or water and inject it through the catheter, while still exerting some pressure on the catheter.
3. Place the other end of the catheter in a drainage basin held below the level of the stoma. Later this process can be carried out at the toilet with drainage delivered into the toilet bowl.
4. After drainage, the catheter is removed and the area around the stoma is gently washed with warm water. Pat dry and apply an absorbent pad over the stoma. Fasten the pad with hypoallergenic tape.

**RATIONALE**

1. When gentle pressure is used, the catheter usually will enter the pouch.
2. This will permit the catheter to enter the pouch.
3. Gravity facilitates drainage. Drainage may include flatus as well as effluent.
4. The entire procedure requires about 5 to 10 min; at first it is performed every 3 h. The time between procedures is gradually lengthened to three times daily.

---

**Chart 38-6**

**Home Care Checklist • Managing Ostomy Care**

At the completion of the home care instruction, the patient or caregiver will be able to:

- Demonstrate ostomy care, including wound cleansing, irrigation, and appliance changing.
- Describe the importance of maintaining peristomal skin integrity.
- Identify sources for obtaining additional dressing and appliance supplies.
- Identify dietary restrictions (foods that can cause diarrhea and constipation).
- Identify measures to be used to promote fluid and electrolyte balance.
- Describe medication regimen: identify medications by name, use, route, and frequency.
- Describe potential complications and necessary actions to be taken if complications occur.
- Identify how to contact enterostomal therapist or home health nurse.

### SMALL BOWEL OBSTRUCTION

**Pathophysiology**

Intestinal contents, fluid, and gas accumulate above the intestinal obstruction. The abdominal distention and retention of fluid reduce the absorption of fluids and stimulate more gastric secretion. With increasing distention, pressure within the intestinal lumen increases, causing a decrease in venous and arteriolar capillary pressure. This causes edema, congestion, necrosis, and eventual rupture or perforation of the intestinal wall, with resultant peritonitis.

Reflux vomiting may be caused by abdominal distention. Vomiting results in a loss of hydrogen ions and potassium from the stomach, leading to a reduction of chlorides and potassium in the blood and to metabolic alkalosis. Dehydration and acidosis develop from loss of water and sodium. With acute fluid losses, hypovolemic shock may occur.

**Clinical Manifestations**

The initial symptom is usually crampy pain that is wavelike and colicky. The patient may pass blood and mucus, but no fecal matter and no flatus. Vomiting occurs. If the obstruction is complete, the peristaltic waves initially become extremely vigorous and eventually assume a reverse direction, with the intestinal contents propelled toward the mouth instead of toward the rectum. If the

---

**FIGURE 38-6** Three causes of intestinal obstruction. (A) Intussusception invagination or shortening of the colon caused by the movement of one segment of bowel into another. (B) Volvulus of the sigmoid colon; the twist is counterclockwise in most cases. Note the edematous bowel. (C) Hernia (inguinal). The sac of the hernia is a continuation of the peritoneum of the abdomen. The hernial contents are intestine, omentum, or other abdominal contents that pass through the hernial opening into the hernial sac.
obstruction is in the ileum, fecal vomiting takes place. First, the patient vomits the stomach contents, then the bile-stained contents of the duodenum and the jejunum, and finally, with each paroxysm of pain, the darker, fecal-like contents of the ileum. The unmistakable signs of dehydration become evident: intense thirst, drowsiness, generalized malaise, aching, and a parched tongue and mucous membranes. The abdomen becomes distended. The lower the obstruction is in the GI tract, the more marked the abdominal distention. If the obstruction continues uncorrected, hypovolemic shock occurs from dehydration and loss of plasma volume.

**Assessment and Diagnostic Findings**

Diagnosis is based on the symptoms described previously and on x-ray findings. Abdominal x-ray studies show abnormal quantities of gas, fluid, or both in the bowel. Laboratory studies (ie, electrolyte studies and a complete blood cell count) reveal a picture of dehydration, loss of plasma volume, and possible infection.

**Medical Management**

Decompression of the bowel through a nasogastric or small bowel tube (see Chap. 36) is successful in most cases. When the bowel is completely obstructed, the possibility of strangulation warrants surgical intervention. Before surgery, intravenous therapy is necessary to replace the depleted water, sodium, chloride, and potassium.

The surgical treatment of intestinal obstruction depends largely on the cause of the obstruction. In the most common causes of obstruction, such as hernia and adhesions, the surgical procedure involves repairing the hernia or dividing the adhesion to which the intestine is attached. In some instances, the portion of affected bowel may be removed and an anastomosis performed. The complexity of the surgical procedure for intestinal obstruction depends on the duration of the obstruction and the condition of the intestine.

**Nursing Management**

Nursing management of the nonsurgical patient with a small bowel obstruction includes maintaining the function of the nasogastric tube, assessing and measuring the nasogastric output, assessing for fluid and electrolyte imbalance, monitoring nutritional status, and assessing improvement (eg, return of normal bowel sounds, decreased abdominal distention, subjective improvement in abdominal pain and tenderness, passage of flatus or stool). The nurse reports discrepancies in intake and output, worsening of pain or abdominal distention, and increased nasogastric output. If the patient’s condition does not improve, the nurse prepares him or her for surgery. The exact nature of the surgery depends on the cause of the obstruction. Nursing care of the patient after surgical repair of a small bowel obstruction is similar to that for other abdominal surgeries (see Chap. 20).

**LARGE BOWEL OBSTRUCTION**

**Pathophysiology**

As in small bowel obstruction, large bowel obstruction results in an accumulation of intestinal contents, fluid, and gas proximal to the obstruction. Obstruction in the large bowel can lead to severe distention and perforation unless some gas and fluid can flow back through the ileal valve. Large bowel obstruction, even if complete, may be undramatic if the blood supply to the colon is not disturbed. If the blood supply is cut off, however, intestinal strangulation and necrosis (ie, tissue death) occur; this condition is life threatening. In the large intestine, dehydration occurs more slowly than in the small intestine because the colon can absorb its fluid contents and can distend to a size considerably beyond its normal full capacity.

**Clinical Manifestations**

Large bowel obstruction differs clinically from small bowel obstruction in that the symptoms develop and progress relatively slowly. In patients with obstruction in the sigmoid colon or the rectum, constipation may be the only symptom for days. Eventually, the abdomen becomes markedly distended, loops of large bowel become visibly outlined through the abdominal wall, and the patient has crampy lower abdominal pain. Finally, fecal vomiting develops. Symptoms of shock may occur.

**Assessment and Diagnostic Findings**

Diagnosis is based on symptoms and on x-ray studies. Abdominal x-ray studies (flat and upright) show a distended colon. Barium studies are contraindicated.

**Medical Management**

A colonscopy may be performed to untwist and decompress the bowel. A cecostomy, in which a surgical opening is made into the cecum, may be performed for patients who are poor surgical risks and urgently need relief from the obstruction. The procedure provides an outlet for releasing gas and a small amount of drainage. A rectal tube may be used to decompress an area that is lower in the bowel. The usual treatment, however, is surgical resection to remove the obstructing lesion. A temporary or permanent colostomy may be necessary. An ileal anastomosis may be performed if it is necessary to remove the entire large colon.

**Nursing Management**

The nurse’s role is to monitor the patient for symptoms that indicate that the intestinal obstruction is worsening and to provide emotional support and comfort. The nurse administers intravenous fluids and electrolytes as prescribed. If the patient’s condition does not respond to nonsurgical treatment, the nurse prepares the patient for surgery. This preparation includes preoperative teaching as the patient’s condition indicates. After surgery, general abdominal wound care and routine postoperative nursing care are provided.

**COLORECTAL CANCER**

Tumors of the colon and rectum are relatively common; the colorectal area (the colon and rectum combined) is now the third most common site of new cancer cases and deaths in the United States. Colorectal cancer is a disease of Western cultures; there were an estimated 148,300 new cases and 56,000 deaths from the disease in 2002 (American Cancer Society, 2002).

The incidence increases with age (the incidence is highest for people older than 85 years of age) and is higher for people with a family history of colon cancer and those with IBD or polyps. The exact cause of colon and rectal cancer is still unknown, but risk factors have been identified (Chart 38-7).
The distribution of cancer sites throughout the colon is shown in Figure 38-7 (Goldman, & Bennett, 2000). Changes in this distribution have occurred in recent years. The incidence of cancer in the sigmoid and rectal areas has decreased, whereas the incidence of cancer in the cecum, ascending, and descending colon has increased.

Improved screening strategies have helped to reduce the number of deaths in recent years. Of the more than 148,000 people diagnosed each year, fewer than half that number die annually (Beyers et al., 2001). Early diagnosis and prompt treatment could save almost three of every four people with colorectal cancer. If the disease is detected and treated at an early stage, the 5-year survival rate is 90%, but only 34% of colorectal cancers are found at an early stage. Survival rates after late diagnosis are very low. Most people are asymptomatic for long periods and seek health care only when they notice a change in bowel habits or rectal bleeding. Prevention and early screening are key to detection and reduction of mortality rates.

Pathophysiology
Cancer of the colon and rectum is predominantly (95%) adenocarcinoma (ie, arising from the epithelial lining of the intestine). It may start as a benign polyp but may become malignant, invade and destroy normal tissues, and extend into surrounding structures. Cancer cells may break away from the primary tumor and spread to other parts of the body (most often to the liver).

Clinical Manifestations
The symptoms are greatly determined by the location of the cancer, the stage of the disease, and the function of the intestinal segment in which it is located. The most common presenting symptom is a change in bowel habits. The passage of blood in the stools is the second most common symptom. Symptoms may also include unexplained anemia, anorexia, weight loss, and fatigue.

The symptoms most commonly associated with right-sided lesions are dull abdominal pain and melena (ie, black, tarry stools). The symptoms most commonly associated with left-sided lesions are those associated with obstruction (ie, abdominal pain and cramping, narrowing stools, constipation, and distention), as well as bright red blood in the stool. Symptoms associated with rectal lesions are tenesmus (ie, ineffective, painful straining at stool), rectal pain, the feeling of incomplete evacuation after a bowel movement, alternating constipation and diarrhea, and bloody stool.

Assessment and Diagnostic Findings
Along with an abdominal and rectal examination, the most important diagnostic procedures for cancer of the colon are fecal occult blood testing, barium enema, proctosigmoidoscopy, and colonoscopy (see Chap. 34). As many as 60% of colorectal cancer cases can be identified by sigmoidoscopy with biopsy or cytology smears (Yamada et al., 1999).

Carcinoembryonic antigen (CEA) studies may also be performed. Although CEA may not be a highly reliable indicator in diagnosing colon cancer because not all lesions secrete CEA, studies show that CEA levels are reliable in predicting prognosis. With complete excision of the tumor, the elevated levels of CEA should return to normal within 48 hours. Elevations of CEA at a later date suggest recurrence (Yamada et al., 1999).

Complications
Tumor growth may cause partial or complete bowel obstruction. Extension of the tumor and ulceration into the surrounding blood vessels results in hemorrhage. Perforation, abscess formation, peri- tonitis, sepsis, and shock may occur.

Gerontologic Considerations
The incidence of carcinoma of the colon and rectum increases with age. These cancers are considered common malignancies in advanced age. Only prostate cancer and lung cancer in men exceed colorectal cancer. Among women, only breast cancer exceeds the incidence of colorectal cancer (Lueckenotte, 2000). Symptoms are often insidious. Cancer patients usually report fatigue, which is caused primarily by iron-deficiency anemia. In early stages, minor changes in bowel patterns and occasional bleeding may occur. The later symptoms most commonly reported by the elderly are abdominal pain, obstruction, tenesmus, and rectal bleeding.

Colon cancer in the elderly has been closely associated with dietary carcinogens. Lack of fiber is a major causative factor because the passage of feces through the intestinal tract is prolonged, which extends exposure to possible carcinogens. Excess fat is believed to alter bacterial flora and convert steroids into compounds that have carcinogenic properties.
Medical Management

The patient with symptoms of intestinal obstruction is treated with intravenous fluids and nasogastric suction. If there has been significant bleeding, blood component therapy may be required.

Treatment for colorectal cancer depends on the stage of the disease (Chart 38-8) and consists of surgery to remove the tumor, supportive therapy, and adjuvant therapy. Data demonstrate delays in tumor recurrence and increases in survival time for patients who receive some form of adjuvant therapy—chemotherapy, radiation therapy, immunotherapy, or multimodality therapy.

ADJUVANT THERAPY

The standard adjuvant therapy administered to patients with Dukes’ class C colon cancer is 5-fluorouracil plus levamisole regimen (Wolfe, 2000). Patients with Dukes’ class B or C rectal cancer are given 5-fluorouracil and high doses of pelvic irradiation. Mitomycin is also used. Radiation therapy is used before, during, and after surgery to shrink the tumor, to achieve better results from surgery, and to reduce the risk of recurrence. For inoperative or unresectable tumors, irradiation is used to provide significant relief from symptoms. Intracavity and implantable devices are used to deliver radiation to the site. The response to adjuvant therapy varies.

SURGICAL MANAGEMENT

Surgery is the primary treatment for most colon and rectal cancers. It may be curative or palliative. Advances in surgical techniques can enable the patient with cancer to have sphincter-saving devices that restore continuity of the GI tract (Tierney et al., 2000). The type of surgery recommended depends on the location and size of the tumor. Cancers limited to one site can be removed through the colonoscope. Laparoscopic colotomy with polypectomy minimizes the extent of surgery needed in some cases. A laparoscope is used as a guide in making an incision into the colon; the tumor mass is then excised. Use of the neodymium/yttrium-aluminum-garnet (Nd:YAG) laser has proved effective with some lesions as well. Bowel resection is indicated for most class A lesions and all class B and C lesions. Surgery is sometimes recommended for class D colon cancer, but the goal of surgery in this instance is palliative; if the tumor has spread and involves surrounding vital structures, it is considered nonresectable.

Surgical procedures include the following:

- Segmental resection with anastomosis (ie, removal of the tumor and portions of the bowel on either side of the growth, as well as the blood vessels and lymphatic nodes) (Fig. 38-8).
- Abdominoperineal resection with permanent sigmoid colostomy (ie, removal of the tumor and a portion of the sigmoid and all of the rectum and anal sphincter) (Fig. 38-9).
- Temporary colostomy followed by segmental resection and anastomosis and subsequent reanastomosis of the colostomy, allowing initial bowel decompression and bowel preparation before resection
- Permanent colostomy or ileostomy for palliation of unresectable obstructing lesions
- Construction of a coloanal reservoir called a colonic J pouch is performed in two steps. A temporary loop ileostomy is constructed to divert intestinal flow, and the newly constructed J pouch (made from 6 to 10 cm of colon) is reattacted to the anal stump. About 3 months after the initial stage, the ileostomy is reversed, and intestinal continuity is restored. The anal sphincter and therefore continence are preserved.

A colostomy is the surgical creation of an opening (ie, stoma) into the colon. It can be created as a temporary or permanent fecal diversion. It allows the drainage or evacuation of colon contents to the outside of the body. The consistency of the drainage is related to the placement of the colostomy, which is dictated by the location of the tumor and the extent of invasion into surrounding tissues (Fig. 38-10). With improved surgical techniques, colostomies are performed on fewer than one third of patients with colorectal cancer.

Gerontologic Considerations

The elderly are at increased risk for complications after surgery and may have difficulty managing colostomy care. They may have decreased vision, impaired hearing, and difficulty with fine motor coordination. It may be helpful for the patient to handle ostomy equipment and simulate cleaning the peristomal skin and irrigating the stoma before surgery. Skin care is a major concern in the elderly ostomate because of the skin changes that occur with aging—the epithelial and subcutaneous fatty layers become thin, and the skin is irritated easily. To prevent skin breakdown, special attention is paid to skin cleansing and the proper fit of ostomy appliances and ileostomy structures, it is considered nonresectable.

Surgical procedures include the following:

- Segmental resection with anastomosis (ie, removal of the tumor and portions of the bowel on either side of the growth, as well as the blood vessels and lymphatic nodes) (Fig. 38-8).
- Abdominoperineal resection with permanent sigmoid colostomy (ie, removal of the tumor and a portion of the sigmoid and all of the rectum and anal sphincter) (Fig. 38-9).
- Temporary colostomy followed by segmental resection and anastomosis and subsequent reanastomosis of the colostomy, allowing initial bowel decompression and bowel preparation before resection
- Permanent colostomy or ileostomy for palliation of unresectable obstructing lesions
- Construction of a coloanal reservoir called a colonic J pouch is performed in two steps. A temporary loop ileostomy is constructed to divert intestinal flow, and the newly constructed J pouch (made from 6 to 10 cm of colon) is reattached to the anal stump. About 3 months after the initial stage, the ileostomy is reversed, and intestinal continuity is restored. The anal sphincter and therefore continence are preserved.

Gerontologic Considerations

The elderly are at increased risk for complications after surgery and may have difficulty managing colostomy care. They may have decreased vision, impaired hearing, and difficulty with fine motor coordination. It may be helpful for the patient to handle ostomy equipment and simulate cleaning the peristomal skin and irrigating the stoma before surgery. Skin care is a major concern in the elderly ostomate because of the skin changes that occur with aging—the epithelial and subcutaneous fatty layers become thin, and the skin is irritated easily. To prevent skin breakdown, special attention is paid to skin cleansing and the proper fit of an appliance. Arteriosclerosis causes decreased blood flow to the wound and stoma site. As a result, transport of nutrients is delayed, and healing time may be prolonged. Some patients have delayed elimination after irrigation because of decreased peristalsis and mucus production. Most patients require 6 months before they feel comfortable with their ostomy care.

NURSING PROCESS: THE PATIENT WITH COLORECTAL CANCER

Assessment

The nurse completes a health history to obtain information about fatigue, abdominal or rectal pain (eg, location, frequency, duration, association with eating or defecation), past and present elimination patterns, and characteristics of stool (eg, color, odor,
consistency, presence of blood or mucus). Additional information includes a history of IBD or colorectal polyps, a family history of colorectal disease, and current medication therapy. The nurse identifies dietary habits, including fat and fiber intake, as well as amounts of alcohol consumed. The nurse describes and documents a history of weight loss.

Assessment includes auscultating the abdomen for bowel sounds and palpating the abdomen for areas of tenderness, distention, and solid masses. Stool specimens are inspected for character and presence of blood.

**Diagnosis**

**NURSING DIAGNOSES**

Based on the assessment data, the major nursing diagnoses may include the following:

- Imbalanced nutrition, less than body requirements, related to nausea and anorexia
- Risk for deficient fluid volume related to vomiting and dehydration
- Anxiety related to impending surgery and the diagnosis of cancer
- Risk for ineffective therapeutic regimen management related to knowledge deficit concerning the diagnosis, the surgical procedure, and self-care after discharge
- Impaired skin integrity related to the surgical incisions (abdominal and perianal), the formation of a stoma, and frequent fecal contamination of peristomal skin
- Disturbed body image related to colostomy
- Ineffective sexuality patterns related to presence of ostomy and changes in body image and self-concept

**COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS**

Potential complications that may develop include the following:

- Intrapertoneal infection
- Complete large bowel obstruction
- GI bleeding
- Bowel perforation
- Peritonitis, abscess, and sepsis

**Planning and Goals**

The major goals for the patient may include attainment of optimal level of nutrition; maintenance of fluid and electrolyte balance; reduction of anxiety; learning about the diagnosis, surgical procedure, and self-care after discharge; maintenance of optimal tissue healing; protection of peristomal skin; learning how to irrigate the colostomy and change the appliance; expressing feelings and concerns about the colostomy and the impact on himself or herself; and avoidance of complications.

**PREPARING THE PATIENT FOR SURGERY**

The patient anticipating surgery for colorectal cancer has many concerns, needs, and fears. He or she may be physically debilitated and emotionally distraught with concern about lifestyle changes after surgery, prognosis, ability to perform in established roles, and finances. Priorities for nursing care include preparing...
the patient physically for surgery, providing information about postoperative care, including stoma care if a colostomy is to be created, and supporting the patient and family emotionally.

Physical preparation for surgery involves building the patient’s stamina in the days preceding surgery and cleansing and sterilizing the bowel the day before surgery. If the patient’s condition permits, the nurse recommends a diet high in calories, protein, and carbohydrates and low in residue for several days before surgery to provide adequate nutrition and minimize cramping by decreasing excessive peristalsis. A full-liquid diet may be prescribed 24 to 48 hours before surgery to decrease bulk. If the patient is hospitalized in the days preceding surgery, PN may be required to replace depleted nutrients, vitamins, and minerals. In some instances, PN may be given at home before surgery. Antibiotics such as sulfonamides, neomycin, and cephalaxin are administered the day before surgery to reduce intestinal bacteria. The bowel is cleansed with laxatives, enemas, or colonic irrigations the evening before and the morning of surgery.

For the patient who is very ill and hospitalized, the nurse measures and records intake and output, including vomitus, to provide an accurate record of fluid balance. The patient’s intake of oral food and fluids may be restricted to prevent vomiting. The nurse administers antiemetics as prescribed. Full or clear liquids may be tolerated, or the patient may be allowed nothing by mouth. A nasogastric tube may be inserted to drain accumulated fluids and prevent abdominal distention. The nurse monitors the abdomen for increasing distention, loss of bowel sounds, and pain or rigidity, which may indicate obstruction or perforation. It also is important to monitor intravenous fluids and electrolytes. Monitoring serum electrolyte levels can detect the hypokalemia and hyponatremia that occur with GI fluid loss. The nurse observes for signs of hypovolemia (e.g., tachycardia, hypotension, decreased pulse volume), assesses hydration status, and reports decreased skin turgor, dry mucous membranes, and concentrated urine.

The nurse assesses the patient’s knowledge about the diagnosis, prognosis, surgical procedure, and expected level of functioning after surgery. It is important to include information about the physical preparation for surgery, the expected appearance and care of the wound, the technique of ostomy care (if applicable), dietary restrictions, pain control, and medication management in the teaching plan (see Plan of Nursing Care 38-1). If the patient will be admitted the day of surgery, the physician’s office may arrange for the patient to be seen by an enterostomal therapist in the days preceding surgery. The ther-

---

**Figure 38-9** Abdominoperineal resection for carcinoma of the rectum.
apast helps determine the optimal site for the stoma and provides teaching about care. If the patient is hospitalized before the day of surgery, the staff enterostomal therapist is involved in the preoperative teaching. All procedures are explained in language the patient understands.

**FIGURE 38-10** A diagrammatic representation of the placement of permanent colostomies. The nature of the discharge varies with the site. Shaded areas show sections of bowel removed. With a sigmoid colostomy (A) the feces are solid. With a descending colostomy (B) the feces are semimushy. With a transverse colostomy (C) the feces are mushy. With an ascending colostomy (D) the feces are fluid.

**PROVIDING EMOTIONAL SUPPORT**

Patients anticipating bowel surgery for colorectal cancer may be very anxious. They may grieve about the diagnosis, the impending surgery, and possible permanent colostomy. Patients undergoing surgery for a temporary colostomy may express fears and concerns similar to those of a person with a permanent stoma. All members of the health care team, including the enterostomal therapy nurse, should be available for assistance and support. The nurse’s role is to assess the patient’s anxiety level and coping mechanisms and suggest methods for reducing anxiety such as deep-breathing exercises and visualizing a successful recovery from surgery and cancer. Other supportive measures include providing privacy and teaching relaxation techniques to the patient. Time is set aside to listen to the patient who wishes to talk, cry, or ask questions. The nurse can arrange a meeting with a spiritual advisor if the patient desires or with the physicians if the patient wishes to discuss the treatment or prognosis. To promote patient comfort, the nurse projects a relaxed, professional, and empathetic attitude. See Nursing Research Profile 38-1 about the importance of spiritual well-being for patients with colorectal cancer.

The patient undergoing a colostomy may find the anticipated changes in body image and lifestyle profoundly disturbing. Because the stoma is located on the abdomen, the patient may think that everyone will be aware of the stoma. The nurse helps reduce this fear by presenting facts about the surgical procedure and the creation and management of the ostomy. If the patient is receptive, the nurse can use diagrams, photographs, and appliances to explain and clarify. Because the patient is experiencing emotional stress, the nurse may need to repeat some of the information. The nurse provides time for the patient and family to ask questions; the nurse’s acceptance and understanding of the patient’s concerns and feelings convey a caring, competent attitude that promotes confidence and cooperation. Consultation with an enterostomal therapist during the preoperative period can be extremely helpful, as can speaking with a person who is successfully managing a colostomy. The United Ostomy Association provides useful information about living with an ostomy through literature, lectures, and exhibits. Visiting services by qualified members and rehabilitation services for new ostomy patients are provided.

**NURSING RESEARCH PROFILE 38-1**

**Spiritual Needs of Patients with Colorectal Cancer**

**Purpose**

Patients with colorectal cancer must be assisted in coping with the demands of the illness and its treatment. Using the Demands of Illness Inventory (DOI) and the Spiritual Well-Being Scale (SWBS), the authors of this descriptive study looked closely at the events that individuals experience in response to a cancer diagnosis and attempted to determine whether those events relate to spiritual well-being. The purpose of the study was to identify the demands of the illness and determine their relationship to spiritual well-being.

**Study Sample and Findings**

The sample for this study consisted of 121 respondents to questionnaires who were at least 21 years old and had been treated for colon, rectal, or anal cancer. Two thirds of the respondents reported a Christian affiliation. Results showed that the illness exerted the greatest demands (highest DOI scores) on those in the youngest age group (21–45 years) and on those with terminal illness. These respondents also reported lower levels of spiritual well-being.

Subjects who reported significantly lower (*p* < .05) DOI levels related to their physical symptoms, monitoring symptoms, and treatment issues also reported higher levels of spiritual well-being.

**Nursing Implications**

Nurses who care for cancer patients must be aware of the intense illness-related demands placed on their patients, especially on those in the younger age range and those with a terminal diagnosis. Nurses should explore interventions to assist patients in coping with these demands, especially interventions to enhance the patients’ spiritual resources.

This study had several limitations. All responses were self-reported, and measures were taken at only one point in time. Other studies need to be conducted to determine whether the findings can be generalized.
PROVIDING POSTOPERATIVE CARE
Postoperative nursing care for patients undergoing colon resection or colostomy is similar to nursing care for any abdominal surgery patient (see Chap. 20), including pain management during the immediate postoperative period. The nurse also monitors the patient for complications such as leakage from the site of the anastomosis, prolapse of the stoma, perforation, stoma retraction, fecal impaction, skin irritation, and pulmonary complications associated with abdominal surgery. The nurse assesses the abdomen for returning peristalsis and assesses the initial stool characteristics. It is important to help patients with a colostomy out of bed on the first postoperative day and encourage them to begin participating in managing the colostomy.

MAINTAINING OPTIMAL NUTRITION
The nurse teaches all patients undergoing surgery for colorectal cancer about the health benefits to be derived from consuming a healthy diet. The diet is individualized as long as it is well balanced and does not cause diarrhea or constipation. The return to normal diet is rapid.

A complete nutritional assessment is important for patients with a colostomy. The patient avoids foods that cause excessive odor and gas, including foods in the cabbage family, eggs, fish, beans, and high-cellulose products such as peanuts. It is important to determine whether the elimination of specific foods is causing any nutritional deficiency. Nonirritating foods are substituted for those that are restricted so that deficiencies are corrected. The nurse advises the patient to experiment with an irritating food several times before restricting it, because an initial sensitivity may decrease with time. The nurse can help the patient identify any foods or fluids that may be causing diarrhea, such as fruits, high-fiber foods, soda, coffee, tea, or carbonated beverages. Paregoric, bismuth subgallate, bismuth subcarbonate, or diphenoxylate with atropine (Lomotil) help control the diarrhea. For constipation, prune or apple juice or a mild laxative is effective. The nurse suggests fluid intake of at least 2 L of fluid per day.

PROVIDING WOUND CARE
The nurse frequently examines the abdominal dressing during the first 24 hours after surgery to detect signs of hemorrhage. It is important to help the patient splint the abdominal incision during coughing and deep breathing to lessen tension on the edges of the incision. The nurse monitors temperature, pulse, and respiratory rate for elevations, which may indicate an infectious process. If the patient has a colostomy, the stoma is examined for swelling (slight edema from surgical manipulation is normal), color (a healthy stoma is pink or red), discharge (a small amount of oozing is normal), and bleeding (an abnormal sign).

If the malignancy has been removed using the perineal route, the perineal wound is observed for signs of hemorrhage. This wound may contain a drain or packing, which is removed gradually. Bits of tissue may slough off for a week. This process is hastened by mechanical irrigation of the wound or with sitz baths performed two or three times each day initially. The condition of the perineal wound and any bleeding, infection, or necrosis are documented.

MONITORING AND MANAGING COMPLICATIONS
The patient is observed for signs and symptoms of complications. It is important to frequently assess the abdomen, including decreasing or changing bowel sounds and increasing abdominal girth, to detect bowel obstruction. The nurse monitors vital signs for increased temperature, pulse, and respirations and for decreased blood pressure, which may indicate an intra-abdominal infectious process. It is important to report rectal bleeding immediately because it indicates hemorrhage. The nurse monitors hematocrit and hemoglobin levels and administers blood component therapy as prescribed. Any abrupt change in abdominal pain is reported promptly. Elevated white blood cell counts and temperature or symptoms of shock are reported because they may indicate sepsis. The nurse administers antibiotics as prescribed.

Pulmonary complications are always a concern with abdominal surgery; patients older than 50 years of age are at risk, especially if they are or have been receiving sedatives or are being maintained on bed rest for a prolonged period. Two primary pulmonary complications are pneumonia and atelectasis. Frequent activity (eg, turning the patient from side to side every 2 hours), deep breathing, coughing, and early ambulation can reduce the risks for these complications. Table 38-6 lists possible postoperative complications.

The incidence of complications related to the colostomy is about one half that seen with an ileostomy. Some common complications are prolapse of the stoma (usually from obesity), perforation (from improper stoma irrigation), stoma retraction, fecal impaction, and skin irritation. Leakage from an anastomotic site can occur if the remaining bowel segments are diseased or weakened. Leakage from an intestinal anastomosis causes abdominal distention and rigidity, temperature elevation, and signs of shock. Surgical repair is necessary.

REMOVING AND APPLYING THE COLOSTOMY APPLIANCE
The colostomy begins to function 3 to 6 days after surgery. The nurse manages the colostomy and teaches the patient about its care until the patient can take over. The nurse teaches skin care and how to apply and remove the drainage pouch. Care of the peristomal skin is an ongoing concern because excoriation or ulceration can develop quickly. The presence of such irritation makes adhering the ostomy appliance difficult, and adhering the ostomy appliance to irritated skin can worsen the skin condition. The effluent discharge and the degree to which it is irritating vary with the type of ostomy. With a transverse colostomy, the stool is soft and mushy and irritating to the skin. With a descending or sigmoid colostomy, the stool is fairly solid and less irritating to the skin. Other skin problems include yeast infections and allergic dermatitis.

If the patient wants to bathe or shower before putting on the clean appliance, micropore tape applied to the sides of the pouch will keep it secure during bathing. To remove the appliance, the patient assumes a comfortable sitting or standing position and gently pushes the skin down from the faceplate while pulling the pouch up and away from the stoma. Gentle pressure prevents the skin from being traumatized and any liquid fecal contents from spilling out. The nurse advises the patient to protect the peristomal skin by then washing the area gently with a moist, soft cloth and a mild soap. Soap acts as a mild abrasive agent to remove enzyme residue from fecal spillage. The patient should remove any excess skin barrier. While the skin is being cleansed, a gauze dressing can cover the stoma, or a vaginal tampon can be inserted gently to absorb excess drainage. After cleansing, the patient pats the skin completely dry with a gauze pad, taking care not to rub the area. The patient can lightly dust nystatin (Mycostatin) powder on the peristomal skin if irritation or yeast growth is present.

Smoothly applying the drainage appliance for a secure fit requires practice and a well-fitting appliance. Patients can choose from a wide variety of appliances, depending on their individual
needs. The stoma is measured to determine the correct size for the pouch; the pouch opening should be about 0.3 cm (1/8 in) larger than the stoma. After the skin is cleansed according to the previously described procedure, the patient applies the peristomal skin barrier (ie, wafer, paste, or powder). Mild skin irritation may require dusting the skin with karaya or Stomahesive powder before attaching the pouch. The patient removes the backing from the adherent surface of the appliance, and places the bag down over the stoma for 30 seconds. The patient empties or changes the drainage appliance when it is one-third to one-fourth full so that the weight of its contents does not cause the appliance to separate from the adhesive disk and spill the contents. Most appliances are disposable and odor resistant; commercially prepared deodorizers are available.

**IRRIGATING THE COLOSTOMY**

The purpose of irrigating a colostomy is to empty the colon of gas, mucus, and feces so that the patient can go about social and business activities without fear of fecal drainage. A stoma does not have voluntary muscular control and may empty at irregular intervals. Regulating the passage of fecal material is achieved by irrigating the colostomy or allowing the bowel to evacuate naturally without irrigations. The choice often depends on the individual and the type of the colostomy. By irrigating the stoma at a regular time, there is less gas and retention of the irrigant. The time for irrigating the colostomy should be consistent with the schedule the person will follow after leaving the hospital. Chart 38-9 delineates the irrigating procedure.

**SUPPORTING A POSITIVE BODY IMAGE**

The patient is encouraged to verbalize feelings and concerns about altered body image and to discuss the surgery and the stoma (if one was created). A supportive environment and a supportive attitude on the nurse’s part are crucial in promoting the patient’s adaptation to the changes brought about by the surgery. If applicable, the patient must learn colostomy care and begin to plan for incorporating stoma care into daily life. The nurse helps the patient overcome aversion to the stoma or fear.
2. Allow some of the solution to flow through the tubing and catheter/cone.
3. Lubricate the catheter/cone and gently insert it into the stoma. Insert the catheter no more than 8 cm (3 in). Hold the shield/cone gently, but firmly, against the stoma to prevent backflow of water.
4. If the catheter does not advance easily, allow water to flow slowly while advancing catheter. *Never force the catheter!*
5. Allow tepid fluid to enter the colon slowly. If cramping occurs, clamp off the tubing and allow the patient to rest before progressing. Water should flow in over a 5- to 10-minute period.
6. Hold the shield/cone in place 10 seconds after the water has been instilled; then gently remove it.
7. Allow 10 to 15 minutes for most of the return; then dry the bottom of the sleeve/sheath and attach it to the top, or apply the appropriate clamp to the bottom of the sleeve.
8. Leave the sleeve/sheath in place for 30 to 45 minutes while the patient gets up and moves around.
9. Cleanse the area with a mild soap and water; pat the area dry.
10. Replace the colostomy dressing or appliance.

1. This helps to control odor and splashing and allows feces and water to flow directly into the commode.
2. Air bubbles in the setup are released so that air is not introduced into the colon, which would cause crampy pain.
3. Lubrication permits ease of insertion of the catheter/cone.
4. A slow rate of flow helps to relax the bowel and facilitates passage of the catheter.
5. Painful cramps usually are caused by too rapid a flow or by too much solution; 300 mL of fluid may be all that is needed to stimulate evacuation. Volume may be increased with subsequent irrigations to 500, 1000, or 1500 mL as needed by the patient for effective results.
6. Most of the water, feces, and flatus will be expelled in 10 to 15 minutes.
7.Ambulation stimulates peristalsis and completion of the irrigation return.
8. Cleanliness and dryness will provide the patient with hours of comfort.
9. The patient should use an appliance until the colostomy is sufficiently controlled. A dressing may be all that is needed.
of self-injury by providing care and teaching in an open, accepting manner and by encouraging the patient to talk about his or her feelings about the stoma.

**DISCUSSING SEXUALITY ISSUES**

The nurse encourages the patient to discuss feelings about sexuality and sexual function. Some patients may initiate questions about sexual activity directly or give indirect clues about their fears. Some may view the surgery as mutilating and a threat to their sexuality; some fear impotence. Others may express worry about odor or leakage from the pouch during sexual activity. Although the appliance presents no deterrent to sexual activity, some patients wear silk or cotton covers and smaller pouches during sex. Alternative sexual positions are recommended, as well as alternative methods of stimulation to satisfy sexual drives. The nurse assesses the patient’s needs and attempts to identify specific concerns. If the nurse is uncomfortable with this or if the patient’s concerns seem complex, it is appropriate for the nurse to seek assistance from an enterostomal therapy nurse, sex counselor or therapist, or advanced practice nurse.

**PROMOTING HOME AND COMMUNITY-BASED CARE**

**Teaching Patients Self-Care**

Patient education and discharge planning require the combined efforts of the physician, nurse, enterostomal therapist, social worker, and dietician. Patients are given specific information, individualized to their needs, about ostomy care and signs and symptoms of potential complications. Dietary instructions are essential to help patients identify and eliminate irritating foods that can cause diarrhea or constipation. It is important to teach patients about their prescribed medications (ie, action, purpose, and possible side effects).

The nurse reviews treatments (eg, irrigations, wound cleansing) and dressing changes and encourages the family to participate. Because the hospital stay is short, the patient may not be able to become proficient in stoma care techniques before discharge. Many patients need referral to a home care agency and the telephone number of the local chapter of the American Cancer Society. The home care nurse goes to the home to provide further care and teaching and to assess how well the patient and family are adjusting to the colostomy. The home environment is assessed for adequacy of resources that allow the patient to accomplish self-care. A family member may assume responsibility for purchasing the equipment and supplies needed at home.

Patients need very specific directions about when to call the physician. They need to know which complications require prompt attention (ie, bleeding, abdominal distention and rigidity, diarrhea, fever, wound drainage, and disruption of suture line). If radiation therapy is planned, the possible side effects (ie, anorexia, vomiting, diarrhea, and exhaustion) are reviewed.

**Continuing Care**

Ongoing care of the patient with cancer and a colostomy often extends well beyond the initial hospital stay. Home care nurses manage ostomy follow-up care, manage the assessment and care of the debilitated patient, and coordinate adjunct therapy. The home care visits also provide the nurse with opportunities to assess the patient’s physical and emotional status and the patient’s and family’s ability to carry out recommended management strategies. Visits from an enterostomal therapy nurse are available to the patient and family as they learn to care for the ostomy and work through their feelings about it, the diagnosis of cancer, and the future. Some patients are interested in and can benefit from involvement in an ostomy support group.

**Evaluation**

**EXPECTED PATIENT OUTCOMES**

Expected patient outcomes may include the following:

1. Consumes a healthy diet
   a. Avoids foods and fluids that cause diarrhea
   b. Substitutes nonirritating foods and fluids for those that are restricted
2. Maintains fluid balance
   a. Experiences no vomiting or diarrhea
   b. Experiences no signs or symptoms of dehydration
3. Feels less anxious
   a. Expresses concerns and fears freely
   b. Uses coping measures to manage stress
4. Acquires information about diagnosis, surgical procedure, preoperative preparation, and self-care after discharge
   a. Discusses the diagnosis, surgical procedure, and postoperative self-care
   b. Demonstrates techniques of ostomy care
5. Maintains clean incision, stoma, and perineal wound
6. Expresses feelings and concerns about self
   a. Gradually increases participation in stoma and peristomal skin care
   b. Discusses feelings related to changed appearance
7. Discusses sexuality in relation to ostomy and to changes in body image
8. Recovers without complications
   a. Is afebrile
   b. Regains normal bowel activity
   c. Exhibits no signs and symptoms of perforation or bleeding

**POLYPS OF THE COLON AND RECTUM**

A polyp is a mass of tissue that protrudes into the lumen of the bowel. Polyps can occur anywhere in the intestinal tract and rectum. They can be classified as neoplastic (ie, adenomas and carcinomas) or non-neoplastic (ie, mucosal and hyperplastic). Non-neoplastic polyps, which are benign epithelial growths, are common in the Western world. They occur more commonly in the large intestine than in the small intestine. Although most polyps do not develop into invasive neoplasms, they must be identified and followed closely. Adenomatous polyps are more common in men. The proportion of these polyps arising in the proximal part of the colon increases with age (after 40 years of age). Prevalence rates vary from 25% to 60%, depending on age. Non-neoplastic polyps occur in 80% of the population, and their frequency increases with age (Wolfe, 2000).

Clinical manifestations depend on the size of the polyp and the amount of pressure it exerts on intestinal tissue. The most common symptom is rectal bleeding. Lower abdominal pain may also occur. If the polyp is large enough, symptoms of obstruction occur. The diagnosis is based on history and digital rectal examination, barium enema studies, sigmoidoscopy, or colonoscopy.

After a polyp is identified, it should be removed. There are several methods: colonoscopy with the use of special equipment (ie, biopsy forceps and snare), laparoscopy, or colonoscopic excision with laparoscopic visualization. The latter technique enables immediate detection of potential problems and allows laparoscopic...
resection and repair of the major complications of perforation and bleeding that may occur with polypectomy. Microscopic examination of the polyp then identifies the type of polyp and indicates what further surgery is required.

**Diseases of the Anorectum**

Anorectal disorders are common, and more than one half of the population will experience one at some time during their lives (Yamada et al., 1999). Patients with anorectal disorders seek medical care primarily because of pain, rectal bleeding, or change in bowel habits. Other common complaints are protrusion of hemorrhoids, anal discharge, perianal itching, swelling, anal tenderness, stenosis, and ulceration. Constipation results from delaying defecation because of anorectal pain.

There has been a steady increase in the frequency of sexually transmitted diseases in recent decades, leading to the identification of new anorectal syndromes. The prevalence of these conditions is increasing. These syndromes include venereal infections such as syphilis, gonorrhea, herpes, chlamydia, and candidiasis, and they are most commonly seen in male homosexuals who practice anorectal intercourse (Wolfe, 2000).

**ANORECTAL ABSCESS**

An anorectal abscess is caused by obstruction of an anal gland, resulting in retrograde infection. People with regional enteritis or immunosuppressive conditions such as AIDS are particularly susceptible to these infections. Many of these abscesses result in fistulas.

An abscess may occur in a variety of spaces in and around the rectum. It often contains a quantity of foul-smelling pus and is painful. If the abscess is superficial, swelling, redness, and tenderness are observed. A deeper abscess may result in toxic symptoms, lower abdominal pain, and fever.

Palliative therapy consists of sitz baths and analgesics. However, prompt surgical treatment to incise and drain the abscess is the treatment of choice. When a deeper infection exists with the possibility of a fistula, the fistulous tract must be excised. If possible, the fistula is excised when the abscess is incised and drained, or a second procedure to do so may be necessary. The wound may be packed with gauze and allowed to heal by granulation.

**ANAL FISTULA**

An anal fistula is a tiny, tubular, fibrous tract that extends into the anal canal from an opening located beside the anus (Fig. 38-11A). Fistulas usually result from an infection. They may also develop from trauma, fissures, or regional enteritis. Pus or stool may leak constantly from the cutaneous opening. Other symptoms may be the passage of flatus or feces from the vagina or bladder, depending on the fistula tract. Untreated fistulas may cause systemic infection with related symptoms.

Surgery is always recommended, because few fistulas heal spontaneously. A fistulectomy (ie, excision of the fistulous tract) is the recommended surgical procedure. The lower bowel is evacuated thoroughly with several prescribed enemas. During surgery, the sinus tract is identified by inserting a probe into it or by injecting the tract with methylene blue solution. The fistula is dissected out or laid open by an incision from its rectal opening to its outlet. The wound is packed with gauze.

**ANAL FISSURE**

An anal fissure is a longitudinal tear or ulceration in the lining of the anal canal (see Fig. 38-11B). Fissures are usually caused by the trauma of passing a large, firm stool or from persistent tightening of the anal canal because of stress and anxiety (leading to constipation). Other causes include childbirth, trauma, and overuse of laxatives.

Extremely painful defecation, burning, and bleeding characterize fissures. Most of these fissures heal if treated by conservative measures, which include stool softeners and bulk agents, an increase in water intake, sitz baths, and emollient suppositories. A suppository combining an anesthetic with a corticosteroid helps relieve the discomfort. Anal dilation under anesthesia may be required.

If fissures do not respond to conservative treatment, surgery is indicated. The procedure considered by most surgeons to be the procedure of choice is the lateral internal sphincterotomy with excision of the fissure; the success rate is 90% to 95% (Rieghley, 1999).

**HEMORRHOIDS**

Hemorrhoids are dilated portions of veins in the anal canal. They are very common. By the age of 50, about 50% of people have hemorrhoids to some extent (Corman, 1998). Shearing of the
mucosa during defecation results in the sliding of the structures in the wall of the anal canal, including the hemorrhoidal and vascular tissues. Increased pressure in the hemorrhoidal tissue due to pregnancy may initiate hemorrhoids or aggravate existing ones. Hemorrhoids are classified as one of two types. Those above the internal sphincter are called internal hemorrhoids, and those appearing outside the external sphincter are called external hemorrhoids (see Fig. 38-11C).

Hemorrhoids cause itching and pain and are the most common cause of bright red bleeding with defecation. External hemorrhoids are associated with severe pain from the inflammation and edema caused by thrombosis (ie, clotting of blood within the hemorrhoid). This may lead to ischemia of the area and eventual necrosis. Internal hemorrhoids are not usually painful until they bleed or prolapse when they become enlarged.

Hemorrhoid symptoms and discomfort can be relieved by good personal hygiene and by avoiding excessive straining during defecation. A high-residue diet that contains fruit and bran along with an increased fluid intake may be all the treatment that is necessary to promote the passage of soft, bulky stools to prevent straining. If this treatment is not successful, the addition of hydrophilic bulk-forming agents such as psyllium and mucilloid may help. Warm compresses, sitz baths, analgesic ointments and suppositories, astringents (eg, witch hazel), and bed rest allow the engorgement to subside.

There are several types of nonsurgical treatments for hemorrhoids. Infrared photocoagulation, bipolar diathermy, and laser therapy are newer techniques that are used to affix the mucosa to the underlying muscle. Injecting sclerosing solutions is also effective for small, bleeding hemorrhoids. These procedures help prevent prolapse.

A conservative surgical treatment of internal hemorrhoids is the rubber-band ligation procedure. The hemorrhoid is visualized through the anoscope, and its proximal portion above the mucocutaneous lines is grasped with an instrument. A small rubber band is then slipped over the hemorrhoid. Tissue distal to the rubber band becomes necrotic after several days and sloughs off. Fibrosis occurs; the result is that the lower anal mucosa is drawn up and adheres to the underlying muscle. Although this treatment has been satisfactory for some patients, it has proven painful for others and may cause secondary hemorrhage. It has been known to cause perianal infection.

Cryosurgical hemorrhoidectomy, another method for removing hemorrhoids, involves freezing the hemorrhoid for a sufficient time to cause necrosis. Although it is relatively painless, this procedure is not widely used because the discharge is very foul smelling and wound healing is prolonged. The Nd:YAG laser is useful in excising hemorrhoids, particularly external hemorrhoidal tags. The treatment is quick and relatively painless. Hemorrhage and abscess are rare postoperative complications.

The previously described methods of treating hemorrhoids are not effective for advanced thrombosed veins, which must be treated by more extensive surgery. Hemorrhoidectomy, or surgical excision, can be performed to remove all the redundant tissue involved in the process. During surgery, the rectal sphincter is usually dilated digitally and the hemorrhoids are removed with a clamp and cautery or are ligated and then excised. After the operative procedures are completed, a small tube may be inserted through the sphincter to permit the escape of flatus and blood; pieces of Gelfoam or Oxycel gauze may be placed over the anal wounds.

### SEXUALLY TRANSMITTED ANORECTAL DISEASES

Three infectious syndromes that are related to sexually transmitted diseases have been identified. Proctitis involves the rectum. It is commonly associated with recent anal-receptive intercourse with an infected partner. Symptoms include a mucopurulent discharge or bleeding, pain in the area, and diarrhea. The pathogens most frequently involved are Neisseria gonorrhoeae (53%), Chlamydia (20%), herpes simplex virus (18%), and Treponema pallidum (9%) (Yamada et al., 1999). Proctocolitis involves the rectum and lowest portion of the descending colon. Symptoms are similar to proctitis but may also include watery or bloody diarrhea, cramps, pain, and bloating. Enteritis involves more of the descending colon, and symptoms include watery, bloody diarrhea: abdominal pain; and weight loss. The most common pathogens causing enteritis are E. histolytica, Giardia lamblia, Shigella, and Campylobacter (Wolfe, 2000).

Sigmoidoscopy is performed to identify portions of the anorectum involved. Samples are taken with rectal swabs, and cultures are obtained to identify the pathogens involved. The treatment of choice for bacterial infections is antibiotics (ie, cefixime, doxycycline, and penicillin). Acyclovir is given to those with viral infections. Infections from E. histolytica and G. lamblia are treated with antiamebic therapy (ie, metronidazole). Ciprofloxacin is an effective treatment for Shigella. Antibiotics of choice for Campylobacter infection are erythromycin and ciprofloxacin.

### PILONIDAL SINUS OR CYST

A pilonidal sinus or cyst is found in the intergluteal cleft on the posterior surface of the lower sacrum (Fig. 38-12). Current theories suggest that it results from local trauma that causes the pen-
The nurse assesses the patient for systemic indicators of excessive bleeding (ie, tachycardia, hypotension, restlessness, and thirst). After hemorrhoidectomy, hemorrhage may occur from the veins that were cut. If a tube has been inserted through the sphincter after surgery, evidence of bleeding may be visible on the dressings. If bleeding is obvious, direct pressure is applied to the area, and the patient is advised to set aside a time for moving the bowels and to heed the urge to defecate as promptly as possible. It may be helpful to have the patient perform relaxation exercises before defecating to relax the abdominal and perineal muscles, which may be constricted or in spasm. Administering an analgesic before a bowel movement is beneficial.

Nursing Interventions

RELIEVING CONSTIPATION

The nurse encourages intake of at least 2 L of water daily to provide adequate hydration and recommends high-fiber foods to promote bulk in the stool and to make it easier to pass fecal matter through the rectum. Bulk laxatives such as Metamucil and stool softeners are administered as prescribed. Patients are more compliant and less apprehensive if they are free of pain. Softeners are administered as prescribed. The patient is advised to set aside a time for moving the bowels and to heed the urge to defecate as promptly as possible. It may be helpful to have the patient perform relaxation exercises before defecating to relax the abdominal and perineal muscles, which may be constricted or in spasm. Administering an analgesic before a bowel movement is beneficial.

REDUCING ANXIETY

Patients facing rectal surgery may be upset and irritable because of discomfort, pain, and embarrassment. The nurse identifies specific psychosocial needs and individualizes the plan of care. The nurse maintains the patient’s privacy while providing care and by limiting visitors, if the patient desires. Soiled dressings are removed from the room promptly to prevent unpleasant odors; room deodorizers may be needed if dressings are foul smelling.

RELIEVING PAIN

During the first 24 hours after rectal surgery, painful spasms of the sphincter and perineal muscles may occur. Control of pain is a prime consideration. The patient is encouraged to assume a comfortable position. Flotation pads under the buttocks when sitting help to decrease the pain, as may ice and analgesic ointments. Warm compresses may promote circulation and soothe irritated tissues. Sitz baths taken three or four times each day can relieve soreness and pain by relaxing sphincter spasm. Twenty-four hours after surgery, topical anesthetic agents may be beneficial in relieving local irritation and soreness. Medications may include topical anesthetics (ie, suppositories), astringents, antiseptics, tranquilizers, and antiemetics. Patients are more compliant and less apprehensive if they are free of pain.

Wet dressings saturated with equal parts of cold water and witch hazel help relieve edema. When wet compresses are being used continuously, the petrolatum is applied around the anal area to prevent skin maceration. The patient is instructed to assume a prone position at intervals because this position promotes dependent drainage of edematous fluid.

PROMOTING URINARY ELIMINATION

Voiding may be a problem after surgery because of a reflex spasm of the sphincter at the outlet of the bladder and a certain amount of muscle guarding from apprehension and pain. The nurse tries all methods to encourage voluntary voiding (ie, increasing fluid intake, listening to running water, and dripping water over the internal and perineal muscles, which may be constricted or in spasm. Control of pain is a prime consideration. The patient is encouraged to assume a comfortable position. Flotation pads under the buttocks when sitting help to decrease the pain, as may ice and analgesic ointments. Warm compresses may promote circulation and soothe irritated tissues. Sitz baths taken three or four times each day can relieve soreness and pain by relaxing sphincter spasm. Twenty-four hours after surgery, topical anesthetic agents may be beneficial in relieving local irritation and soreness. Medications may include topical anesthetics (ie, suppositories), astringents, antiseptics, tranquilizers, and antiemetics. Patients are more compliant and less apprehensive if they are free of pain.

Wet dressings saturated with equal parts of cold water and witch hazel help relieve edema. When wet compresses are being used continuously, the petrolatum is applied around the anal area to prevent skin maceration. The patient is instructed to assume a prone position at intervals because this position promotes dependent drainage of edematous fluid.

MONITORING AND MANAGING COMPLICATIONS

The operative site is examined frequently for rectal bleeding. The nurse assesses the patient for systemic indicators of excessive bleeding (ie, tachycardia, hypotension, restlessness, and thirst). After hemorrhoidectomy, hemorrhage may occur from the veins that were cut. If a tube has been inserted through the sphincter after surgery, evidence of bleeding may be visible on the dressings. If bleeding is obvious, direct pressure is applied to the area, and the physician is notified. It is important to avoid using moist heat because it encourages vessel dilation and bleeding.
PROMOTING HOME AND COMMUNITY-BASED CARE

Teaching Patients Self-Care
Most patients with anorectal conditions are not hospitalized. Those who have surgical procedures to correct the condition often are discharged directly from the outpatient surgical center. If they are hospitalized, it is for a short time, usually only 24 hours. Patient teaching is essential to facilitate recovery at home.

The nurse instructs the patient to keep the perianal area as clean as possible by gently cleansing with warm water and then drying with absorbent cotton wipes. The patient avoids rubbing the area with toilet tissue. Instructions are provided about how to take a sitz bath and how to test the temperature of the water. Sitz baths may be given in the bathtub or plastic sitz bath unit three or four times each day. Sitz baths should follow each bowel movement for 1 to 2 weeks after surgery. The nurse encourages the patient to respond quickly to the urge to defecate to prevent constipation. The diet is modified to increase fluids and fiber. Moderate exercise is encouraged, and the patient is taught about the prescribed diet, the significance of proper eating habits and exercise, and the laxatives that can be taken safely.

Evaluation

EXPECTED PATIENT OUTCOMES
Expected patient outcomes may include the following:

1. Attains a normal pattern of elimination
   a. Sets aside a time for defecation, usually after a meal or at bedtime
   b. Responds to the urge to defecate and takes the time to sit on the toilet and try to defecate
   c. Uses relaxation exercises as needed
   d. Increases fluid intake to 2 L per day
   e. Adds high-fiber foods to diet
   f. Reports passage of soft, formed stools
   g. Reports decreased abdominal discomfort
2. Is less anxious
3. Has less pain
   a. Modifies body position and activities to minimize pain and discomfort
   b. Applies warmth or cold to anorectal area
   c. Takes sitz baths four times each day
4. Voids without difficulty
5. Adheres to the therapeutic regimen
   a. Keeps perianal area dry
   b. Eats bulk-forming foods
   c. Has a soft, formed stool on a regular basis
6. Exhibits no evidence of complications
   a. Has a clean incision
   b. Has normal vital signs
   c. Shows no signs of hemorrhage

Critical Thinking Exercises
1. You are caring for an elderly man who was just admitted to the hospital. He complains that he has had pain throughout his abdomen for the past 2 days. He states that his bowel patterns have changed recently and that he has not had a bowel movement in 4 days. He has not eaten since yesterday. He states he has no appetite and that he is concerned because he has type 2 diabetes mellitus. When you complete your initial nursing assessment, you notice that his abdomen is distended and rigid and that bowel sounds are absent throughout all fields. Analyze these findings, indicate what you think the possible causes may be, and explain the actions you would take and why. Explain how this man’s diagnosis of diabetes mellitus affects his plan of nursing care and his medical management.

2. During a conversation with a neighbor, you learn that she has recently seen her doctor and that she has been diagnosed with IBS. She asks you to help her understand this process and to explain the reason for the dietary restrictions her doctor has given her. Her doctor also prescribed a laxative and an antidepressant. She explains the amount of stress she has been under at work. Identify the facts that you know about this process and how the actions of the doctor would help in this situation. What will you tell your neighbor?

3. You are caring for a patient who has been diagnosed with colon cancer. He recently underwent a colonoscopy where the growth was detected in the lower portion of the descending colon. The patient is scheduled for a colon resection. You know that he will return from surgery with a sigmoid colostomy. What will you need to do during the preoperative period to prepare your patient for this surgery? What will be the nursing diagnoses and related interventions that are a priority during the immediate postoperative period? Explain how you would meet the postoperative emotional and health education needs of the patient with a colostomy.

4. You are assigned to a general medical clinic. Two patients with inflammatory bowel disease arrive for their appointments. One of the patients, a 52-year-old woman, has recently been diagnosed with Crohn’s disease. The other patient, a 21-year-old woman, was diagnosed with ulcerative colitis at 15 years of age and has had an ileostomy since the age of 19 years. Compare the two disease processes in terms of their pathophysiology, clinical manifestations, course of the illness, and therapeutic management. What similarities and differences would you expect to find in the nutritional and pharmacologic therapies for these two patients? What assessment parameters would you use to identify the psychosocial needs of each of these patients.

Assessment and Management of Patients With Hepatic Disorders

**LEARNING OBJECTIVES**

On completion of this chapter, the learner will be able to:

1. Identify the metabolic functions of the liver and the alterations in these functions that occur with liver disease.
2. Explain liver function tests and the clinical manifestations of liver dysfunction in relation to pathophysiologic alterations of the liver.
3. Relate jaundice, portal hypertension, ascites, varices, nutritional deficiencies, and hepatic coma to pathophysiologic alterations of the liver.
4. Describe the medical, surgical, and nursing management of patients with esophageal varices.
5. Compare the various types of hepatitis and their causes, prevention, clinical manifestations, management, prognosis, and home health care needs.
6. Use the nursing process as a framework for care of the patient with cirrhosis of the liver.
7. Compare the nonsurgical and surgical management of patients with cancer of the liver.
8. Describe the postoperative nursing care of the patient undergoing liver transplantation.
Liver disorders are common and may result from a virus or exposure to toxic substances such as alcohol. Another liver disorder is cancer: hepatocellular carcinoma is a highly malignant tumor that is difficult to treat and often fatal. In the United States, hepatocellular cancer accounts for less than 1% of all cancers, but in other parts of the world, it accounts for up to 50% of cancer cases. The difference is thought to be due to the percentage of the population who are carriers of the hepatitis B virus, which predisposes individuals to hepatocellular cancer. Liver cancer can originate in the liver or can metastasize to the liver from other sites.

Liver function is complex, and liver dysfunction affects all body systems. For this reason, the nurse must understand how the liver functions and must have expert assessment and clinical management skills to care for patients undergoing complex diagnostic and treatment procedures. The nurse also must understand technological advances in the management of liver disorders.

**ANATOMY OF THE LIVER**

The liver, the largest gland of the body, can be considered a chemical factory that manufactures, stores, alters, and excretes a large number of substances involved in metabolism. The location of the liver is essential in this function, because it receives nutrient-rich blood directly from the gastrointestinal (GI) tract and then either stores or transforms these nutrients into chemicals that are used elsewhere in the body for metabolic needs. The liver is especially important in the regulation of glucose and protein metabolism. The liver manufactures and secretes bile, which has a major role in the digestion and absorption of fats in the GI tract. It removes waste products from the bloodstream and secretes them into the bile. The bile produced by the liver is stored temporarily in the gallbladder until it is needed for digestion, at which time the gallbladder empties and bile enters the intestine (Fig. 39-1).

**ANATOMIC AND PHYSIOLOGIC OVERVIEW**

The liver, the largest gland of the body, can be considered a chemical factory that manufactures, stores, alters, and excretes a large number of substances involved in metabolism. The location of the liver is essential in this function, because it receives nutrient-rich blood directly from the gastrointestinal (GI) tract and then either stores or transforms these nutrients into chemicals that are used elsewhere in the body for metabolic needs. The liver is especially important in the regulation of glucose and protein metabolism. The liver manufactures and secretes bile, which has a major role in the digestion and absorption of fats in the GI tract. It removes waste products from the bloodstream and secretes them into the bile. The bile produced by the liver is stored temporarily in the gallbladder until it is needed for digestion, at which time the gallbladder empties and bile enters the intestine (Fig. 39-1).

**ANATOMY OF THE LIVER**

The liver is located behind the ribs in the upper right portion of the abdominal cavity. It weighs about 1,500 g and is divided into four lobes. A thin layer of connective tissue surrounds each lobe, extending into the lobe itself and dividing the liver mass into small units called lobules (O’Grady, Lake & Howdle, 2000).

The circulation of the blood into and out of the liver is of major importance in its function. The blood that perfuses the liver comes from two sources. Approximately 75% of the blood supply comes from the portal vein, which drains the GI tract and is rich in nutrients. The remainder of the blood supply enters by way of the hepatic artery and is rich in oxygen. Terminal branches of these two blood supplies join to form common capillary beds, which constitute the sinusoids of the liver (Fig. 39-2). Thus, a mixture of venous and arterial blood bathes the liver cells (hepatocytes). The sinusoids empty into a venule that occupies the center of each liver lobule and is called the central vein. The central veins join to form the hepatic vein, which constitutes the venous drainage of the liver and empties into the inferior vena cava, close to the diaphragm. Thus, there are two sources of blood flowing into the liver and only one exit pathway (O’Grady et al., 2000).

In addition to hepatocytes, phagocytic cells belonging to the reticuloendothelial system are present in the liver. Other organs that contain reticuloendothelial cells are the spleen, bone marrow,
lymph nodes, and lungs. In the liver, these cells are called Kupffer cells. Their main function is to engulf particulate matter (such as bacteria) that enters the liver through the portal blood.

The smallest bile ducts, called canaliculi, are located between the lobules of the liver. The canaliculi receive secretions from the hepatocytes and carry them to larger bile ducts, which eventually form the hepatic duct. The hepatic duct from the liver and the cystic duct from the gallbladder join to form the common bile duct, which empties into the small intestine. The sphincter of Oddi, located at the junction where the common bile duct enters the duodenum, controls the flow of bile into the intestine. Disorders of the gallbladder are described in Chapter 40.

**FUNCTIONS OF THE LIVER**

**Glucose Metabolism**

The liver plays a major role in the metabolism of glucose and the regulation of blood glucose concentration. After a meal, glucose is taken up from the portal venous blood by the liver and converted into glycogen, which is stored in the hepatocytes. Subsequently, the glycogen is converted back to glucose and released as needed into the bloodstream to maintain normal levels of blood glucose. Additional glucose can be synthesized by the liver through a process called gluconeogenesis. For this process, the liver uses amino acids from protein breakdown or lactate produced by exercising muscles (Bacon & Di Bisceglie, 2000).

**Ammonia Conversion**

Use of amino acids from protein for gluconeogenesis results in the formation of ammonia as a byproduct. The liver converts this metabolically generated ammonia into urea. Ammonia produced by bacteria in the intestines is also removed from portal blood for urea synthesis. In this way, the liver converts ammonia, a potential toxin, into urea, a compound that can be excreted in the urine.

**Protein Metabolism**

The liver also plays an important role in protein metabolism. It synthesizes almost all of the plasma proteins (except gamma globulin), including albumin, alpha and beta globulins, blood clotting factors, specific transport proteins, and most of the plasma lipoproteins. Vitamin K is required by the liver for synthesis of prothrombin and some of the other clotting factors. Amino acids serve as the building blocks for protein synthesis.

**Fat Metabolism**

The liver is also active in fat metabolism. Fatty acids can be broken down for the production of energy and the production of ketone bodies (acetoacetic acid, beta-hydroxybutyric acid, and acetone). Ketone bodies are small compounds that can enter the bloodstream and provide a source of energy for muscles and other tissues. Breakdown of fatty acids into ketone bodies occurs primarily when the availability of glucose for metabolism is limited, as during starvation or in uncontrolled diabetes. Fatty acids and their metabolic products are also used for the synthesis of cholesterol, lecithin, lipoproteins, and other complex lipids. Under some conditions, lipids may accumulate in the hepatocytes, resulting in the abnormal condition called fatty liver.

**Vitamin and Iron Storage**

Vitamins A, B, and D and several of the B-complex vitamins are stored in large amounts in the liver. Certain substances, such as iron and copper, are also stored in the liver. Because the liver is rich in these substances, liver extracts have been used for therapy for a wide range of nutritional disorders.

**Drug Metabolism**

The liver metabolizes many medications, such as barbiturates, opioids, sedative agents, anesthetics, and amphetamines. Metabolism generally results in loss of activity of the medication, although in some cases activation of the medication may occur. One of the important pathways for medication metabolism involves conjugation (binding) of the medication with a variety of compounds, such as glucuronic or acetic acid, to form more soluble substances. The conjugated products may be excreted in the feces or urine, similar to bilirubin excretion. If an oral medication (absorbed from the GI tract) is metabolized by the liver to a great extent before it reaches the systemic circulation (first-pass effect), the amount of medication actually reaching the systemic circulation (oral bioavailability) will be decreased. Bioavailability is the fraction of the administered drug that reaches the systemic circulation. Some medications have such a large first-pass effect that their use is essentially limited to the parenteral route, or oral doses must be substantially larger than parenteral doses to achieve the same effect.

**Bile Formation**

Bile is continuously formed by the hepatocytes and collected in the canaliculi and bile ducts. It is composed mainly of water and electrolytes such as sodium, potassium, calcium, chloride, and bicarbonate, and it also contains significant amounts of lecithin, fatty acids, cholesterol, bilirubin, and bile salts. Bile is collected
Bilirubin Excretion

Bilirubin is a pigment derived from the breakdown of hemoglobin by cells of the reticuloendothelial system, including the Kupffer cells of the liver. Hepatocytes remove bilirubin from the blood and chemically modify it through conjugation to glucuronic acid, which makes the bilirubin more soluble in aqueous solutions. The conjugated bilirubin is secreted by the hepatocytes into the adjacent bile canaliculi and is eventually carried in the bile into the duodenum.

In the small intestine, bilirubin is converted into urobilinogen, which is in part excreted in the feces and in part absorbed through the intestinal mucosa into the portal blood. Much of this reabsorbed urobilinogen is removed by the hepatocytes and is secreted into the bile once again (enterohepatic circulation). Some of the urobilinogen enters the systemic circulation and is excreted by the kidneys in the urine. Elimination of bilirubin in the bile represents the major route of excretion for this compound.

The bilirubin concentration in the blood may be increased in the presence of liver disease, when the flow of bile is impeded (ie, with gallstones in the bile ducts), or with excessive destruction of red blood cells. With bile duct obstruction, bilirubin does not enter the intestine; as a consequence, urobilinogen is absent from the urine and decreased in the stool. Biliary tract disorders are discussed in Chapter 40.

Gerontologic Considerations

The Gerontologic Considerations Box outlines age-related changes in the liver. The most common change in the liver in the elderly is a decrease in its size and weight, accompanied by a decrease in total hepatic blood flow. In general, however, these decreases are proportional to the decreases in body size and weight seen in normal aging. Results of liver function tests do not normally change in the elderly; abnormal results in an elderly patient indicate abnormal liver function and are not the result of the aging process itself.

The immune system is altered in the aged, and a less responsive immune system may be responsible for the increased incidence and severity of hepatitis B in the elderly and the increased incidence of liver abscesses secondary to decreased phagocytosis by the Kupffer cells. With the advent of hepatitis B vaccine as the standard for prevention, the incidence of hepatic diseases may decrease in the future.

Metabolism of medications by the liver appears to decrease in the elderly, but such changes are usually accompanied by changes in intestinal absorption, renal excretion, and altered body distribution of some medications secondary to changes in fat deposition. These alterations necessitate careful medication administration and monitoring; if appropriate, reduced dosages may be needed to prevent medication toxicity.

Assessment

HEALTH HISTORY

If liver function test results are abnormal, the patient may need to be evaluated for liver disease. In such cases, the health history will focus on exposure of the patient to hepatotoxic substances or infectious agents. The patient’s occupational, recreational, and travel history may assist in identifying exposure to hepatotoxins (eg, industrial chemicals, other toxins) responsible for illness. The patient’s history of alcohol and drug use, including but not limited to the use of injectable drugs, provides additional information about exposure to toxins and infectious agents. Many medications (including acetaminophen, ketoconazole, and valproic acid) are responsible for hepatic dysfunction and disease. A careful medical history to assess hepatic dysfunction should address all prescribed and over-the-counter medications, herbal remedies, and dietary supplements used by the patient currently and in the past.

Lifestyle behaviors that increase the risk for exposure to infectious agents are identified. Injectable drug use, sexual practices, and a history of foreign travel are all potential risk factors for liver disease. The amount and type of alcohol consumption are identified using screening tools (questionnaires) that have been developed for this purpose (see Chap. 5). The history also includes an evaluation of the patient’s past medical history to identify risk factors for the development of liver disease. Current and past medical conditions, including those of a psychological or psychiatric nature, are identified. The family history includes questions about familial liver disorders that may have their etiology in alcohol abuse or gallstone disease, as well as other familial or genetic diseases, such as hemochromatosis, Wilson’s disease, or alpha-1 antitrypsin disease (see “Genetics in Nursing Practice” in Chap. 42).

The history also includes reviewing symptoms that suggest liver disease. Symptoms that may have their etiology in liver disease but are not specific to hepatic dysfunction include jaundice, malaise, weakness, fatigue, pruritus, abdominal pain, fever, anorexia,
weight gain, edema, increasing abdominal girth, hematemesis, melena, hematocchezia (passage of bloody stools), easy bruising, decreased libido in men and secondary amenorrhea in women, changes in mental acuity, personality changes, and sleep disturbances.

**PHYSICAL EXAMINATION**

The nurse assesses the patient for physical signs that may occur with liver dysfunction, including pallor of chronic illness and jaundice. The skin, mucosa, and sclerae are inspected for jaundice, and the extremities are assessed for muscle atrophy, edema, and skin excoriation secondary to scratching. The nurse observes the skin for petechiae or ecchymotic areas (bruises), spider angiomas, and palmar erythema. The male patient is assessed for unilateral or bilateral gynecomastia and testicular atrophy due to endocrine changes. The patient’s cognitive status (recall, memory, abstract thinking) and neurologic status are assessed. The nurse observes for general tremor, asterixis, weakness, and slurred speech. These symptoms are discussed later.

The nurse assesses the abdomen for dilated abdominal wall veins, ascites, and a fluid wave (discussed later). The abdomen is palpated to assess liver size and to detect any tenderness over the liver. The liver may be palpable in the right upper quadrant. A palpable liver presents as a firm, sharp ridge with a smooth surface (Fig. 39-3). The nurse estimates liver size by percussing its upper and lower borders. When the liver is not palpable but tenderness is suspected, tapping the lower right thorax briskly may elicit tenderness. For comparison, the nurse then performs a similar maneuver on the left lower thorax.

If the liver is palpable, the examiner notes and records its size and consistency, whether it is tender, and whether its outline is regular or irregular. If the liver is enlarged, the degree to which it descends below the right costal margin is recorded to provide some indication of its size. The examiner determines whether the liver’s edge is sharp and smooth or blunt, and whether the enlarged liver is nodular or smooth. The liver of a patient with cirrhosis is small and hard, whereas the liver of a patient with acute hepatitis is soft, and the hand easily moves the edge.

Tenderness of the liver implies recent acute enlargement with consequent stretching of the liver capsule. The absence of tenderness may imply that the enlargement is of long-standing duration. The liver of a patient with viral hepatitis is tender, whereas that of a patient with alcoholic hepatitis is not. Enlargement of the liver is an abnormal finding requiring evaluation.

**Diagnostic Evaluation**

**LIVER FUNCTION TESTS**

More than 70% of the parenchyma of the liver may be damaged before liver function test results become abnormal. Function is generally measured in terms of serum enzyme activity (e.g., alkaline phosphatase, lactic dehydrogenase, serum aminotransferases) and serum concentrations of proteins (albumin and globulins), bilirubin, ammonia, clotting factors, and lipids. Several of these tests may be helpful for assessing patients with liver disease. However, the nature and extent of hepatic dysfunction cannot be determined by these tests alone, as many other disorders can affect their results.

Serum aminotransferases (also called transaminases) are sensitive indicators of injury to the liver cells and are useful in detecting acute liver disease such as hepatitis. Alanine aminotransferase (ALT) (formerly called serum glutamic-pyruvic transaminase [SGPT]), aspartate aminotransferase (AST) (formerly called serum glutamic-oxaloacetic transaminase [SGOT]), and gamma glutamyl transferase (GGT) (also called G-glutamyl transpeptidase) are the most frequently used tests of liver damage. ALT levels increase primarily in liver disorders and may be used to monitor the course of hepatitis or cirrhosis or the effects of treatments that may be toxic to the liver. AST is present in tissues that have high metabolic activity; thus, the level may be increased if there is damage to or death of tissues of organs such as the heart, liver, skeletal muscle, and kidney. Although not specific to liver disease, levels of AST may be increased in cirrhosis, hepatitis, and liver cancer. Increased GGT levels are associated with cholestasis but can also be due to alcoholic liver disease. Although the kidney has the highest level of the enzyme, the liver is considered the source of normal serum activity. The test determines liver cell dysfunction and is a sensitive indicator of cholestasis. Its main value in liver disease is confirming the hepatic origin of an elevated alkaline phosphatase level. Common liver function tests are listed in Table 39-1.

**LIVER BIOPSY**

Liver biopsy is the removal of a small amount of liver tissue, usually through needle aspiration. It permits examination of liver cells. The most common indication is to evaluate diffuse disorders of the parenchyma and to diagnose space-occupying lesions. Liver biopsy is especially useful when clinical findings and laboratory tests are not diagnostic. Bleeding and bile peritonitis after liver biopsy are the major complications; therefore, coagulation studies are obtained, their values are noted, and abnormal results are treated before liver biopsy is performed. Other techniques for liver biopsy are preferred if ascites or coagulation abnormalities exist. A liver biopsy can be performed percutaneously under ultrasound guidance or transvenously through the right internal jugular vein to right hepatic vein under fluoroscopic control. Liver biopsy can also be performed laparoscopically. Nursing responsibilities related to percutaneous liver biopsy are summarized in Chart 39-1.

</tbody>
</table>
NURSING ACTIVITIES | RATIONALE
--- | ---
**PREPROCEDURE**
1. Ascertain that results of coagulation tests (prothrombin time, partial thromboplastin time, and platelet count) are available and that compatible donor blood is available.
2. Check for signed consent; confirm that informed consent has been provided.
3. Measure and record the patient’s pulse, respirations, and blood pressure immediately before biopsy.
4. Describe to the patient in advance: steps of the procedure; sensations expected; after-effects anticipated; restrictions of activity and monitoring procedures to follow.

Many patients with liver disease have clotting defects and are at risk for bleeding.

Prebiopsy values provide a basis on which to compare the patient’s vital signs and evaluate status after the procedure.

Explanations allay fears and ensure cooperation.

Encouragement and support of the nurse enhance comfort and promote a sense of security.

The skin at the site of penetration will be cleansed and a local anesthetic will be infiltrated.

Holding the breath immobilizes the chest wall and the diaphragm; penetration of the diaphragm thereby is avoided, and the risk of lacerating the liver is minimized.

**DURING PROCEDURE**
5. Support the patient during the procedure.
6. Expose the right side of the patient’s upper abdomen (right hypochondriac).
7. Instruct the patient to inhale and exhale deeply several times, finally to exhale, and to hold breath at the end of expiration. The physician promptly introduces the biopsy needle by way of the transthoracic (intercostal) or transabdominal (subcostal) route, penetrates the liver, aspirates, and withdraws.
8. Instruct the patient to resume breathing.

Encouragement and support of the nurse enhance comfort and promote a sense of security.

The skin at the site of penetration will be cleansed and a local anesthetic will be infiltrated.

Holding the breath immobilizes the chest wall and the diaphragm; penetration of the diaphragm thereby is avoided, and the risk of lacerating the liver is minimized.

**POSTPROCEDURE**
9. Immediately after the biopsy, assist the patient to turn onto the right side; place a pillow under the costal margin, and caution the patient to remain in this position, recumbent and immobile, for several hours. Instruct the patient to avoid coughing or straining.
10. Measure and record the patient’s pulse, respiratory rate, and blood pressure at 10- to 15-minute intervals for the first hour, then every 30 minutes for the next 1 to 2 hours or until the patient’s condition stabilizes.
11. If the patient is discharged after the procedure, instruct the patient to avoid heavy lifting and strenuous activity for 1 week.

In this position, the liver capsule at the site of penetration is compressed against the chest wall, and the escape of blood or bile through the perforation is prevented.

Changes in vital signs may indicate bleeding, severe hemorrhage, or bile peritonitis, the most frequent complications of liver biopsy.

Activity restriction reduces the risk of bleeding at the biopsy puncture site.
OTHER DIAGNOSTIC TESTS

Ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) are used to identify normal structures and abnormalities of the liver and biliary tree. A radioisotope liver scan may be performed to assess liver size and hepatic blood flow and obstruction.

Laparoscopy (insertion of a fiber-optic endoscope through a small abdominal incision) is used to examine the liver and other pelvic structures. It is also used to perform guided liver biopsy, to determine the etiology of ascites, and to diagnose and stage tumors of the liver and other abdominal organs.

Hepatic Dysfunction

Hepatic dysfunction results from damage to the liver’s parenchymal cells, either directly from primary liver diseases or indirectly from obstruction of bile flow or derangements of hepatic circulation. Liver dysfunction may be acute or chronic; chronic dysfunction is far more common than acute.

Chronic liver disease, including cirrhosis, is the seventh most common cause of death in the United States among young and middle-aged adults. More than 40% of those deaths are associated with alcohol. The rate of chronic liver disease for men is twice that for women, and chronic liver disease is more common among African Americans than Caucasians.

Disease processes that lead to hepatocellular dysfunction may be caused by infectious agents such as bacteria and viruses and by anoxia, metabolic disorders, toxins and medications, nutritional deficiencies, and hypersensitivity states. The most common cause of parenchymal damage is malnutrition, especially that related to alcoholism.

The parenchymal cells respond to most noxious agents by replacing glycogen with lipids, producing fatty infiltration with or without cell death or necrosis. This is commonly associated with inflammatory cell infiltration and growth of fibrous tissue. Cell regeneration can occur if the disease process is not too toxic to the cells. The result of chronic parenchymal disease is the shrunken, fibrotic liver seen in cirrhosis.

The consequences of liver disease are numerous and varied. Their ultimate effects are often incapacitating or life-threatening, and their presence is ominous. Treatment often is difficult. Among the most common and significant symptoms of liver disease are the following:

- Jaundice, resulting from increased bilirubin concentration in the blood
- Portal hypertension, ascites, and varices, resulting from circulatory changes within the diseased liver and producing severe GI hemorrhages and marked sodium and fluid retention
- Nutritional deficiencies, which result from the inability of the damaged liver cells to metabolize certain vitamins; responsible for impaired functioning of the central and peripheral nervous systems and for abnormal bleeding tendencies
- Hepatic encephalopathy or coma, reflecting accumulation of ammonia in the serum due to impaired protein metabolism by the diseased liver

JAUNDICE

When the bilirubin concentration in the blood is abnormally elevated, all the body tissues, including the sclerae and the skin, become yellow-tinged or greenish-yellow, a condition called jaundice. Jaundice becomes clinically evident when the serum bilirubin level exceeds 2.5 mg/dL (43 fmol/L). Increased serum bilirubin levels and jaundice may result from impairment of hepatic uptake, conjugation of bilirubin, or excretion of bilirubin into the biliary system. There are several types of jaundice: hemolytic, hepatocellular, obstructive, or jaundice due to hereditary hyperbilirubinemia. Hepatocellular and obstructive jaundice are the two types commonly associated with liver disease.

Hemolytic Jaundice

Hemolytic jaundice is the result of an increased destruction of the red blood cells, the effect of which is to flood the plasma with bilirubin so rapidly that the liver, although functioning normally, cannot excrete the bilirubin as quickly as it is formed. This type of jaundice is encountered in patients with hemolytic transfusion reactions and other hemolytic disorders. The bilirubin in the blood of these patients is predominantly of the unconjugated, or free, type. Fecal and urine urobilinogen levels are increased, but the urine is free of bilirubin. Patients with this type of jaundice, unless their hyperbilirubinemia is extreme, do not experience symptoms or complications as a result of the jaundice per se. Prolonged jaundice, however, even if mild, predisposes to the formation of pigment stones in the gallbladder, and extremely severe jaundice (levels of free bilirubin exceeding 20 to 25 mg/dL) poses a risk for brain stem damage.

Hepatocellular Jaundice

Hepatocellular jaundice is caused by the inability of damaged liver cells to clear normal amounts of bilirubin from the blood. The cellular damage may be from infection, such as in viral hepatitis (eg, hepatitis A, B, C, D, or E) or other viruses that affect the liver (eg, yellow fever virus, Epstein-Barr virus), from medication or chemical toxicity (eg, carbon tetrachloride, chloroform, phosphorus, arsenicals, certain medications), or from alcohol. Cirrhosis of the liver is a form of hepatocellular disease that may produce jaundice. It is usually associated with excessive alcohol intake, but it may also be a late result of liver cell necrosis caused by viral infection. In prolonged obstructive jaundice, cell damage eventually develops, so that both types appear together.

Patients with hepatocellular jaundice may be mildly or severely ill, with lack of appetite, nausea, malaise, fatigue, weakness, and possible weight loss. In some cases of hepatocellular disease, jaundice may not be obvious. The serum bilirubin concentration and urine urobilinogen level may be elevated. In addition, AST and ALT levels may be increased, indicating cellular necrosis. The patient may report headache, chills, and fever if the cause is infectious. Depending on the cause and extent of the liver cell damage, hepatocellular jaundice may or may not be completely reversible.

Obstructive Jaundice

Obstructive jaundice of the extrahepatic type may be caused by occlusion of the bile duct by a gallstone, an inflammatory process, a tumor, or pressure from an enlarged organ. The obstruction may also involve the small bile ducts within the liver (ie, intrahepatic obstruction), caused, for example, by pressure on these channels from inflammatory swelling of the liver or by an inflammatory exudate within the ducts themselves. Intrahepatic obstruction resulting from stasis and inspissation (thickening) of bile within the canaliculi may occur after the ingestion of certain medications,
which are referred to as cholestatic agents. These include phenothiazines, antithyroid medications, sulfonylureas, tricyclic antidepressant agents, nitrofurantoin, androgens, and estrogens.

Whether the obstruction is intrahepatic or extrahepatic, and whatever its cause may be, bile cannot flow normally into the intestine but is backed up into the liver substance. It is then reabsorbed into the blood and carried throughout the entire body, staining the skin, mucous membranes, and sclerae. It is excreted in the urine, which becomes deep orange and foamy. Because of the decreased amount of bile in the intestinal tract, the stools become light or clay-colored. The skin may itch intensely, requiring repeated soothing baths. Dyspepsia and intolerance to fatty foods may develop because of impaired fat digestion in the absence of intestinal bile. AST, ALT, and GGT levels generally rise only moderately, but bilirubin and alkaline phosphatase levels are elevated.

**Hereditary Hyperbilirubinemia**

Increased serum bilirubin levels (hyperbilirubinemia) resulting from several inherited disorders can also produce jaundice. Gilbert’s syndrome is a familial disorder characterized by an increased level of unconjugated bilirubin that causes jaundice. Although serum bilirubin levels are increased, liver histology and liver function test results are normal, and there is no hemolysis. This syndrome affects 2% to 5% of the population.

Other conditions that are probably caused by inborn errors of biliary metabolism include Dubin–Johnson syndrome (chronic idiopathic jaundice, with pigment in the liver) and Rotor’s syndrome (chronic familial conjugated hyperbilirubinemia without pigment in the liver); “benign” cholestatic jaundice of pregnancy, with retention of conjugated bilirubin, probably secondary to unusual sensitivity to the hormones of pregnancy; and probably also benign recurrent intrahepatic cholestasis.

**PORTAL HYPERTENSION**

Obstructed blood flow through the damaged liver results in increased blood pressure (portal hypertension) throughout the portal venous system. Although portal hypertension is commonly associated with hepatic cirrhosis, it can also occur with noncirrhotic liver disease. While splenomegaly (enlarged spleen) with possible hypersplenism is a common manifestation of portal hypertension, two major consequences of portal hypertension are ascites and varices.

In ascites, fluid accumulates in the abdominal cavity. Although ascites is often a result of liver damage, it may also occur with disorders such as cancer, kidney disease, and heart failure. Varices are varicosities that develop from elevated pressures transmitted to all of the veins that drain into the portal system. They are prone to rupture and often are the source of massive hemorrhages from the upper GI tract and the rectum. In addition, blood clotting abnormalities, often seen in patients with severe liver disease, increase the likelihood of bleeding.

**ASCITES**

**Pathophysiology**

The mechanisms responsible for the development of ascites are not completely understood. Portal hypertension and the resulting increase in capillary pressure and obstruction of venous blood flow through the damaged liver are contributing factors. The failure of the liver to metabolize aldosterone increases sodium and water retention by the kidney. Sodium and water retention, increased intravascular fluid volume, and decreased synthesis of albumin by the damaged liver all contribute to fluid moving from the vascular system into the peritoneal space. Loss of fluid into the peritoneal space causes further sodium and water retention by the kidney in an effort to maintain the vascular fluid volume, and the process becomes self-perpetuating.

As a result of liver damage, large amounts of albumin-rich fluid, 15 L or more, may accumulate in the peritoneal cavity as ascites. With the movement of albumin from the serum to the peritoneal cavity, the osmotic pressure of the serum decreases. This, combined with increased portal pressure, results in movement of fluid into the peritoneal cavity (Fig. 39-4).

**Clinical Manifestations**

Increased abdominal girth and rapid weight gain are common presenting symptoms of ascites. The patient may be short of breath and uncomfortable from the enlarged abdomen, and striae and distended veins may be visible over the abdominal wall. Fluid and electrolyte imbalances are common.

**Assessment and Diagnostic Evaluation**

The presence and extent of ascites are assessed by percussion of the abdomen. When fluid has accumulated in the peritoneal cavity, the flanks bulge when the patient assumes a supine position. The presence of fluid can be confirmed either by percussing for shifting dullness or by detecting a fluid wave (Fig. 39-5). A fluid wave is likely to be found only when a large amount of fluid is present.

![FIGURE 39-4 Pathogenesis of ascites (arterial vasodilation theory).](image-url)
Assessing for abdominal fluid wave. The examiner places the hands along the side of the patient’s flank, then strikes one flank sharply, detecting any fluid wave with the other hand. An assistant’s hand is placed (ulnar side down) along the patient’s midline to prevent the fluid wave from being transmitted through the tissues of the abdominal wall.

**Medical Management**

**DIETARY MODIFICATION**

The goal of treatment for the patient with ascites is a negative sodium balance to reduce fluid retention. Table salt, salty foods, salted butter and margarine, and all ordinary canned and frozen foods (foods that are not specifically prepared for low-sodium diets) should be avoided. It may take 2 to 3 months for the patient’s taste buds to adjust to unsalted foods. In the meantime, the taste of unsalted foods can be improved by using salt substitutes such as lemon juice, oregano, and thyme. Commercial salt substitutes need to be approved by the physician because those containing ammonia could precipitate hepatic coma. Most salt substitutes contain potassium and should be avoided if the patient has impaired renal function. The patient should make liberal use of powdered, low-sodium milk and milk products. If fluid accumulation is not controlled with this regimen, the daily sodium allowance may be reduced further to 500 mg, and diuretics may be administered.

Dietary control of ascites via strict sodium restriction is difficult to achieve at home. The likelihood that the patient will follow even a 2-g sodium diet increases if the patient and the person preparing meals understand the rationale for the diet and receive periodic guidance about selecting and preparing appropriate foods. Approximately 10% of patients with ascites respond to these measures alone. Nonresponders and those who find sodium restriction difficult require diuretic therapy.

**DIURETICS**

Use of diuretics along with sodium restriction is successful in 90% of patients with ascites. Spironolactone (Aldactone), an aldosterone-blocking agent, is most often the first-line therapy in patients with ascites from cirrhosis. When used with other diuretics, spironolactone helps prevent potassium loss. Oral diuretics such as furosemide (Lasix) may be added but should be used cautiously because with long-term use they may also induce severe sodium depletion (hyponatremia).

Ammonium chloride and acetazolamide (Diamox) are contraindicated because of the possibility of precipitating hepatic coma. Daily weight loss should not exceed 1 to 2 kg (2.2 to 4.4 lb) in patients with ascites and peripheral edema or 0.5 to 0.75 kg (1.1 to 1.65 lb) in patients without edema. Fluid restriction is not attempted unless the serum sodium concentration is very low.

Possible complications of diuretic therapy include fluid and electrolyte disturbances (including hypovolemia, hypokalemia, hyponatremia, and encephalopathy). Encephalopathy may be precipitated by dehydration and hypovolemia. Also, when potassium stores are depleted, the amount of ammonia in the systemic circulation increases, which may cause impaired cerebral functioning and encephalopathy.

**BED REST**

In patients with ascites, an upright posture is associated with activation of the renin-angiotensin-aldosterone system and sympathetic nervous system (Porth, 2002). This results in reduced renal glomerular filtration and sodium excretion and a decreased response to loop diuretics. Bed rest may be a useful therapy, especially for patients whose condition is refractory to diuretics.

**PARACENTESIS**

Paracentesis is the removal of fluid (ascites) from the peritoneal cavity through a small surgical incision or puncture made through the abdominal wall under sterile conditions. Ultrasound guidance may be indicated in some patients at high risk for bleeding because of an abnormal coagulation profile or in those who have had previous abdominal surgery and who may have adhesions. Paracentesis was once considered a routine form of treatment for ascites but is now performed primarily for diagnostic examination of ascitic fluid, for treatment of massive ascites that is resistant to nutritional and diuretic therapy and that is causing severe problems to the patient, and as a prelude to diagnostic imaging studies, peritoneal dialysis, or surgery. A sample of the ascitic fluid may be sent to the laboratory for analysis. Cell count, albumin and total protein levels, culture, and occasionally other tests are performed.

Use of large-volume (5 to 6 liters) paracentesis has been shown to be a safe method for treating patients with severe ascites. This technique, in combination with the intravenous infusion of salt-poor albumin or other colloid, has become the standard treatment for refractory, massive ascites (Krige & Beckingham, 2001; Menon & Kamath, 2000). The salt-poor albumin helps reduce edema by causing the ascitic fluid to be drawn back into the bloodstream and ultimately eliminated by the kidneys. The procedure provides only temporary removal of fluid; it rapidly recurs, necessitating repeated removal. Nursing care of the patient undergoing paracentesis is presented in Chart 39-2.

**OTHER METHODS OF TREATMENT**

Insertion of a peritoneovenous shunt to redirect ascitic fluid from the peritoneal cavity into the systemic circulation is a treatment modality for ascites, but this procedure is seldom used because of the high complication rate and high incidence of shunt failure. The shunt is reserved for those who are resistant to diuretic therapy, are not candidates for liver transplantation, have abdominal adhesions, or are ineligible for other procedures because of severe medical conditions, such as cardiac disease.
Nursing Management

If a patient with ascites from liver dysfunction is hospitalized, nursing measures include assessment and documentation of intake and output, abdominal girth, and daily weight to assess fluid status. The nurse monitors serum ammonia and electrolyte levels to assess electrolyte balance, response to therapy, and indicators of encephalopathy.

PROMOTING HOME AND COMMUNITY-BASED CARE

Teaching Patients Self-Care. The patient treated for ascites is likely to be discharged with some ascites still present. Before hospital discharge, the nurse teaches the patient and family about the treatment plan, including the need to avoid all alcohol intake, adhere to a low-sodium diet, take medications as prescribed, and check with the physician before taking any new medications (Chart 39-3). Additional patient and family teaching addresses skin care and the need to weigh the patient daily and to watch for and report signs and symptoms of complications.

Continuing Care. A referral for home care may be warranted, especially if the patient lives alone or cannot provide self-care. The home visit enables the nurse to assess changes in the patient’s condition and weight, abdominal girth, skin, and cognitive and emotional status. The home care nurse assesses the home environment and the availability of resources needed to adhere to the treatment plan (eg, a scale to obtain daily weights, facilities to prepare and store appropriate foods, resources to purchase needed medications). It is important to assess the patient’s adherence to the treatment plan and the ability to buy, prepare, and eat
appropriate foods. The nurse reinforces previous teaching and emphasizes the need for regular follow-up and the importance of keeping scheduled health care appointments.

**ESOPHAGEAL VARICES**

Bleeding or hemorrhage from esophageal varices occurs in approximately one third of patients with cirrhosis and varices. The mortality rate resulting from the first bleeding episode is 45% to 50%; it is one of the major causes of death in patients with cirrhosis (Pomier-Layrargues, Villeneuve, Deschenes et al., 2001). The mortality rate increases with each subsequent bleeding episode.

**Pathophysiology**

Esophageal varices are dilated, tortuous veins usually found in the submucosa of the lower esophagus, but they may develop higher in the esophagus or extend into the stomach. This condition nearly always is caused by portal hypertension, which in turn is due to obstruction of the portal venous circulation within the damaged liver.

Because of increased obstruction of the portal vein, venous blood from the intestinal tract and spleen seeks an outlet through collateral circulation (new pathways of return to the right atrium). The effect is increased pressure, particularly in the vessels in the submucosal layer of the lower esophagus and upper part of the stomach. These collateral vessels are not very elastic but rather are tortuous and fragile and bleed easily (Fig. 39-6). Less common causes of varices are abnormalities of the circulation in the splenic vein or superior vena cava and hepatic venous thrombosis.

Bleeding esophageal varices are life-threatening and can result in hemorrhagic shock, producing decreased cerebral, hepatic, and renal perfusion. In turn, there is an increased nitrogen load from bleeding into the GI tract and an increased serum ammonia level, increasing the risk for encephalopathy. Usually the dilated veins cause no symptoms unless the portal pressure increases sharply and the mucosa or supporting structures become thin. Then massive hemorrhage takes place.

Factors that contribute to hemorrhage are muscular exertion from lifting heavy objects; straining at stool; sneezing, coughing, or vomiting; esophagitis; irritation of vessels by poorly chewed foods or irritating fluids; or reflux of stomach contents (especially alcohol). Salicylates and any medication that erodes the esophageal mucosa or interferes with cell replication also may contribute to bleeding.

**Clinical Manifestations**

The patient with bleeding esophageal varices may present with hematemesis, melena, or general deterioration in mental or physical status and often has a history of alcohol abuse. Signs and symptoms may include:

- Hematemesis: Blood in vomit.
- Melena: Black, tarry stools.
- Altered mental status: Confusion, disorientation, agitation.
- Decreased urine output:

**Physiology/Pathophysiology**

- **Portal hypertension** (caused by resistance to portal flow and increased portal venous inflow)
- **Development of pressure gradient of 12 mm Hg or greater between portal vein and inferior vena cava (portal pressure gradient)**
- **Venous collaterals develop from high portal system pressure to systemic veins in esophageal plexus, hemorrhoidal plexus and retroperitoneal veins**
- **Abnormal varicoid vessels form in any of above locations**
- **Vessels may rupture causing life-threatening hemorrhage.**

**Figure 39-4** Pathogenesis of bleeding esophageal varices.
symptoms of shock (cool clammy skin, hypotension, tachycardia) may be present.

**Assessment and Diagnostic Findings**

Endoscopy is used to identify the bleeding site, along with barium swallow, ultrasonography, CT, and angiography.

**ENDOSCOPY**

Immediate endoscopy (see Chap. 34) is indicated to identify the cause and the site of bleeding; at least 30% of patients suspected of bleeding from esophageal varices bleed from other sources (gastritis, ulcers). Nursing support can be effective in relieving anxiety during this often-stressful experience. Careful monitoring can detect early signs of cardiac dysrhythmias, perforation, and hemorrhage.

After the examination, fluids are not given until the gag reflex returns. Lozenges and gargles may be used to relieve throat discomfort if the patient’s physical condition and mental status permit. If the patient is actively bleeding, oral intake will not be permitted and the patient will be prepared for further diagnostic and therapeutic procedures.

**PORTAL HYPERTENSION MEASUREMENTS**

Portal hypertension may be suspected if dilated abdominal veins and hemorrhoids are detected. A palpable enlarged spleen (splenomegaly) and ascites may also be present. Portal venous pressure can be measured directly or indirectly. Indirect measurement of the hepatic vein pressure gradient is the most common procedure; it requires insertion of a fluid-filled balloon catheter into the antecubital or femoral vein. The catheter is advanced under fluoroscopy to a hepatic vein. A “wedged” pressure (similar to pulmonary artery wedge pressure) is obtained by occluding the blood flow in the blood vessel; pressure in the unoccluded vessel is also measured. Although the values obtained may underestimate portal pressure, this measurement may be obtained several times to evaluate the results of therapy.

Direct measurement of portal vein pressure can be obtained by several methods. During laparotomy, a needle may be introduced into the spleen; a manometer reading of more than 20 mL saline is abnormal. Another direct measurement requires insertion of a catheter into the portal vein or one of its branches. Endoscopic measurement of pressure within varices is used only in conjunction with endoscopic sclerotherapy.

**LABORATORY TESTS**

Laboratory tests may include various liver function tests, such as serum aminotransferase, bilirubin, alkaline phosphatase, and serum proteins. Splenopexy, which involves serial or segmental x-rays, is used to detect extensive collateral circulation in esophageal vessels, which would indicate varices. Other tests are hepatoportography and celiac angiography. These are usually performed in the operating room or radiology department.

**Medical Management**

Bleeding from esophageal varices can quickly lead to hemorrhagic shock and is an emergency. This patient is critically ill, requiring aggressive medical care and expert nursing care, and is usually transferred to the intensive care unit for close monitoring and management. See Chapter 15 for a discussion of care of the patient in shock.

The extent of bleeding is evaluated and vital signs are monitored continuously when hematemesis and melena are present. Signs of potential hypovolemia are noted, such as cold clammy skin, tachycardia, a drop in blood pressure, decreased urine output, restlessness, and weak peripheral pulses. Blood volume is monitored by a central venous pressure or arterial catheter. Oxygen is administered to prevent hypoxia and to maintain adequate blood oxygenation.

Because patients with bleeding esophageal varices have intravascular volume depletion and are subject to electrolyte imbalance, intravenous fluids with electrolytes and volume expanders are provided to restore fluid volume and replace electrolytes. Transfusion of blood components also may be required. An indwelling urinary catheter is usually inserted to permit frequent monitoring of urine output.

A variety of pharmacologic, endoscopic, and surgical approaches are used to treat bleeding esophageal varices, but none is ideal and most are associated with considerable risk to the patient. Non-surgical treatment of bleeding esophageal varices is preferable because of the high mortality rate of emergency surgery for control of bleeding esophageal varices and because of the poor physical condition of the patient with severe liver dysfunction.

**PHARMACOLOGIC THERAPY**

In an actively bleeding patient, medications are administered initially because they can be obtained and administered quickly; other therapies take longer to initiate. Vasopressin (Pitressin) may be the initial mode of therapy because it produces constriction of the splanchnic arterial bed and a resulting decrease in portal pressure. It may be administered intravenously or by intra-arterial infusion (Menon & Kamath, 2000). Either method requires close monitoring by the nurse. Vital signs and the presence or absence of blood in the gastric aspirate indicate the effectiveness of vasopressin. Monitoring of fluid intake and output and electrolyte levels is necessary because hyponatremia may occur and vasopressin may have an antidiuretic effect. Coronary artery disease is a contraindication to the use of vasopressin, because coronary vasoconstriction is a side effect that may precipitate myocardial infarction.

The combination of vasopressin and nitroglycerin (administered by the intravenous, sublingual, or transdermal route) has been effective in reducing or preventing the side effects (constriction of coronary vessels and angina) caused by vasopressin alone.

Somatostatin and octreotide (Sandostatin) have been reported to be more effective than vasopressin in decreasing bleeding from esophageal varices without the vasoconstrictive effects of vasopressin. These medications cause selective splanchnic vasoconstriction. Propranolol (Inderal) and nadolol (Corgard), beta-blocking agents that decrease portal pressure, have been shown to prevent bleeding from esophageal varices in some patients; however, it is recommended that they be used only in combination with other treatment modalities such as sclerotherapy, variceal banding, or balloon tamponade. Nitrates such as isosorbide (Isordil) lower portal pressure by venodilation and decreased cardiac output. Further studies of these and other medications are necessary to evaluate their use in the treatment and prevention of bleeding episodes.

**BALLOON TAMPOONADE**

To control hemorrhage in certain patients, balloon tamponade may be used. In this procedure, pressure is exerted on the cardia (upper orifice of the stomach) and against the bleeding varices by a double-balloon tamponade (Sengstaken-Blakemore tube) (Fig. 39-7). The tube has four openings, each with a specific purpose: gastric aspiration, esophageal aspiration, inflation of the gastric balloon, and inflation of the esophageal balloon.

The balloon in the stomach is inflated with 100 to 200 mL of air. An x-ray confirms proper positioning of the gastric balloon. Then the tube is pulled gently to exert a force against the gastric
cardia. Traction may be applied with weights or by attachment to a football helmet. Irrigation of the tubing is performed to detect bleeding; if returns are clear, the esophageal balloon is not inflated. If bleeding continues, the esophageal balloon is inflated. The desired pressure in the esophageal and gastric balloons is 25 to 40 mm Hg, as measured by the manometer. There is a possibility of injury or rupture of the esophagus with inflation of the esophageal balloon, so constant nursing surveillance is necessary.

Gastric suction is provided by connecting the gastric catheter outlet to suction. The tubing is irrigated hourly, and drainage will indicate whether bleeding has been controlled. Room-temperature lavage or irrigation may be used in the gastric balloon. The pressure within the esophageal balloon is measured and recorded every 2 to 4 hours via the manometer to detect underinflation or over-inflation with potential for esophageal injury. When it appears that bleeding has stopped, the balloons are carefully and sequentially deflated. The esophageal balloon is deflated first and the patient is monitored for recurrent bleeding. After several hours without bleeding, the gastric balloon may be deflated safely. If there is still no bleeding, the tamponade tube is removed. The therapy is used for as short a time as possible to control bleeding while emergency treatment is completed and definitive therapies are instituted (no longer than 24 hours).

Although balloon tamponade has been fairly successful, there are some inherent dangers. Displacement of the tube and the inflated balloon into the oropharynx can cause life-threatening obstruction of the airway and asphyxiation. This may occur if a patient pulls on the tube because of confusion or discomfort. It may also result from rupture of the gastric balloon, allowing the esophageal balloon to move into the oropharynx. Sudden rupture of the balloon causes airway obstruction and aspiration of gastric contents into the lungs. The tube is tested before insertion to minimize this risk. Aspiration of blood and secretions into the lungs is frequently associated with balloon tamponade, especially in the stuporous or comatose patient. Endotracheal intubation before insertion of the tube protects the airway and minimizes the risk of aspiration. Ulceration and necrosis of the nose, the mucosa of the stomach, or the esophagus may occur if the tube is left in place or inflated too long or at too high a pressure.

**NURSING ALERT** The patient being treated with balloon tamponade must never be left alone because of the risk for serious complications. The patient must be monitored closely and continuously. Precautions must be taken to ensure that the patient does not pull on or inadvertently displace the tube.

**FIGURE 39-7** Esophageal balloon tamponade to treat esophageal varices. (A) Dilated, bleeding esophageal veins (varices) of the lower esophagus. (B) A four-lumen esophageal tamponade tube with balloons (uninflated) in place. (C) Compression of bleeding esophageal varices by inflated esophageal and gastric balloons. The gastric and esophageal outlets permit the nurse to aspirate secretions.
These potential complications necessitate intensive and expert care. A confused or restless patient with this tube in place and balloons inflated requires close monitoring to prevent its displacement. Nursing measures include frequent mouth and nasal care. For secretions that accumulate in the mouth, tissues should be within easy reach of the patient. Oral suction may be necessary to remove oral secretions. Because of the many potential complications, balloon tamponade tubes are used only as a temporary measure.

The patient with esophageal hemorrhage is usually extremely anxious and frightened. Knowing that the nurse is nearby and will respond immediately can help alleviate some of this anxiety. Tube insertion is uncomfortable and never pleasant. Explanation during the procedure and while the tube is in place may be reassuring to the patient.

Although the use of balloon tamponade stops the bleeding in 90% of patients, bleeding recurs in 60% to 70%, necessitating other treatment modalities (eg, sclerotherapy or banding) (Menon & Kamath, 2000). Once the balloons are deflated or the tube is removed, the patient must be assessed frequently because of the high risk for recurrent bleeding.

**ENDOSCOPIC SCLEROTHERAPY**

In endoscopic **sclerotherapy** (Fig. 39-8) (also referred to as injection sclerotherapy), a sclerosing agent is injected through a fiberoptic endoscope into the bleeding esophageal varices to promote thrombosis and eventual sclerosis. The procedure has been used successfully to treat acute GI hemorrhage (Menon & Kamath, 2000; O’Grady et al., 2000). Endoscopic variceal sclerotherapy has been used in the primary prophylaxis of variceal bleeding, but the results are poorer than those of pharmacotherapy (Sarin, Lamba, Kumar et al., 1999).

After treatment, the patient must be observed for bleeding, perforation of the esophagus, aspiration pneumonia, and esophageal stricture. Antacids may be administered after the procedure to counteract the effects of peptic reflux.

**ESOPHAGEAL BANDING THERAPY**

**VARICEAL BANDING**

In variceal **banding** (Fig. 39-9), a modified endoscope loaded with an elastic rubber band is passed through an overtube directly onto the varix (or varices) to be banded. After suctioning the bleeding varix into the tip of the endoscope, the rubber band is slipped over the tissue, causing necrosis, ulceration, and eventual sloughing of the varix.

**VARICEAL BANDING THERAPY**

**VARICEAL BANDING**

In variceal **banding** (Fig. 39-9), a modified endoscope loaded with an elastic rubber band is passed through an overtube directly onto the varix (or varices) to be banded. After suctioning the bleeding varix into the tip of the endoscope, the rubber band is slipped over the tissue, causing necrosis, ulceration, and eventual sloughing of the varix.

**Variceal banding is comparable to endoscopic sclerotherapy in the effective control of bleeding.** Compared with sclerotherapy, variceal banding also significantly reduces rebleeding rates, mortality, procedure-related complications, and the number of sessions needed to eradicate varices. Complications include superficial ulceration and dysphagia, transient chest discomfort, and rarely esophageal strictures (Menon & Kamath, 2000). Recently, endoscopic variceal band ligation has been shown to be safe and more effective than propranolol for preventing a first bleeding episode (Sarin et al., 1999).

**TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNTING**

Transjugular intrahepatic portosystemic shunting (TIPS) is a method of treating esophageal varices in which a cannula is threaded into the portal vein by the transjugular route. An expandable stent is inserted and serves as an intrahepatic shunt between the portal circulation and the hepatic vein (Fig. 39-10), reducing portal hypertension.

Creation of a TIPS is indicated for the treatment of recurrent variceal bleeding refractory to pharmacologic or endoscopic therapy. It has also been indicated for the control of refractory ascites. This technique is also used as a bridge to liver transplantation. Complications may include bleeding, sepsis, heart failure, organ perforation, shunt thrombosis, and progressive liver failure (Pomier-Layrargues et al., 2001).

**SURGICAL MANAGEMENT**

Several surgical procedures have been developed to treat esophageal varices and to minimize rebleeding, but they are often accompanied by significant risk. Procedures that may be used for esophageal varices are direct surgical ligation of varices; splenorenal, mesocaval, and portacaval venous shunts to relieve portal pressure; and esophageal transection with devascularization. Use of these procedures is controversial, and studies regarding their effectiveness and outcomes are ongoing (Bacon & Di Bisceglie, 2000).

**Surgical Bypass Procedures.** Surgical decompression of the portal circulation can prevent variceal bleeding if the shunt remains patent (Bacon & Di Bisceglie, 2000). One of the various surgical shunting procedures (Fig. 39-11) is the distal splenorenal shunt made between the splenic vein and the left renal vein after splenectomy. A mesocaval shunt is created by anastomosing the superior mesenteric vein to the proximal end of the vena cava or to the side of the vena cava using grafting material. The goal of distal splenorenal and mesocaval shunts is to drain only a portion of venous blood from the portal bed to decrease portal pressure; thus, they are considered selective shunts. The liver continues to receive some portal flow, and the incidence of encephalopathy may be reduced. Portacaval shunts divert all portal flow to the vena cava via end-to-side or side-to-side approaches, so they are considered nonselective shunts.

These procedures are extensive and are not always successful because of secondary thrombosis in the veins used for the shunt as well as complications (eg, encephalopathy, accelerated liver failure). The efficacy of these procedures has been studied extensively. The most recent studies have found that all shunts are equally effective in preventing recurrent variceal bleeding but may cause further impairment of liver function and encephalopathy. Partial portacaval shunts with interposition grafts are as effective as other shunts but are associated with a lower rate of encephalopathy (de Franchis, 2000; Krieger & Beckingham, 2001; Orozco & Mercado, 2000). The severity of the disease (by Child’s classification) and the
potential for future liver transplantation guide the physician’s choice of intervention. If the cause of portal hypertension is the rare Budd-Chiari syndrome or other venous obstructive disease, a portacaval or a mesoatrial shunt may be performed (see Fig. 39-11). The mesoatrial shunt is required when the infrahepatic vena cava is thrombosed and must be bypassed.

**Devascularization and Transection.** Devascularization and staple-gun transection procedures to separate the bleeding site from the high-pressure portal system have been used in the emergency management of variceal bleeding. The lower end of the esophagus is reached through a small gastrostomy incision; a staple gun permits anastomosis of the transected ends of the esophagus. Rebleeding is a risk, and the outcomes of these procedures vary among patient populations.

---

**NURSING ALERT** Postoperative care is similar to that for any abdominal surgery, but the risk for complications (hypovolemic or hemorrhagic shock, hepatic encephalopathy, electrolyte imbalance, metabolic and respiratory alkalosis, alcohol withdrawal syndrome, and seizures) is high. The surgical procedures do not alter the course of the progressive liver disease, and bleeding may recur as new collateral vessels develop.

---

**FIGURE 39-9** Esophageal banding. (A) A rubber band–like ligature is slipped over an esophageal varix via an endoscope. (B) Necrosis results and the varix eventually sloughs off.

**FIGURE 39-10** Transjugular intrahepatic portosystemic shunt (TIPS). A stent is inserted via catheter to the portal vein to divert blood flow and reduce portal hypertension.

**FIGURE 39-11** Portal systemic shunts. Normal portal system is shown in (A); examples of portal shunts to reduce portal pressure are shown in (B) to (D).
initiated to keep the stomach as empty as possible and to prevent straining and vomiting. The patient often complains of severe thirst, which may be relieved by frequent oral hygiene and moist sponges to the lips. The nurse closely monitors the blood pressure. Vitamin K therapy and multiple blood transfusions often are indicated because of blood loss. A quiet environment and calm reassurance may help to relieve the patient’s anxiety and reduce agitation.

Bleeding anywhere in the body is anxiety-provoking, resulting in a crisis for the patient and family. If the patient has been a heavy user of alcohol, delirium secondary to alcohol withdrawal can complicate the situation. The nurse provides support and explanations regarding medical and nursing interventions. Monitoring the patient closely will help in detecting and managing complications.

Management modalities and nursing care of the patient with bleeding esophageal varices are summarized in Table 39-2.

**HEPATIC ENCEPHALOPATHY AND COMA**

Hepatic encephalopathy, a life-threatening complication of liver disease, occurs with profound liver failure and may result from the accumulation of ammonia and other toxic metabolites in the blood. Hepatic coma represents the most advanced stage of hepatic encephalopathy. Some researchers describe a false or weak neurotransmitter as a cause, but the exact mechanism is not fully understood. These false neurotransmitters may be generated from an intestinal source and result in the precipitation of encephalopathy. Many other theories exist about the causes of encephalopathy, including excess tryptophan and its metabolites.

*Several modalities may be used concurrently or in sequence.*
and endogenous benzodiazepines or opiates. Benzodiazepine-like chemicals (compounds) have been detected in the plasma and cerebrospinal fluid of patients with hepatic encephalopathy due to cirrhosis (Bacon & Di Bisceglie, 2000).

Portal-systemic encephalopathy, the most common type of hepatic encephalopathy, occurs primarily in patients with cirrhosis with portal hypertension and portal-systemic shunting.

Pathophysiology
Ammonia accumulates because damaged liver cells fail to detoxify and convert to urea the ammonia that is constantly entering the bloodstream. Ammonia enters the bloodstream as a result of its absorption from the GI tract and its liberation from kidney and muscle cells. The increased ammonia concentration in the blood causes brain dysfunction and damage, resulting in hepatic encephalopathy.

Circumstances that increase serum ammonia levels tend to aggravate or precipitate hepatic encephalopathy. The largest source of ammonia is the enzymatic and bacterial digestion of dietary and blood proteins in the GI tract. Ammonia from these sources is increased as a result of GI bleeding (ie, bleeding esophageal varices or chronic GI bleeding), a high-protein diet, bacterial infections, and uremia. The ingestion of ammonium salts also increases the blood ammonia level. In the presence of alkalosis or hypokalemia, increased amounts of ammonia are absorbed from the GI tract and from the renal tubular fluid. Conversely, serum ammonia is decreased by elimination of protein from the diet and by the administration of antibiotic agents, such as neomycin sulfate, that reduce the number of intestinal bacteria capable of converting urea to ammonia (Dudek, 2001).

Other factors unrelated to increased serum ammonia levels that may cause hepatic encephalopathy in susceptible patients include excessive diuresis, dehydration, infections, surgery, fever, and some medications (sedative agents, tranquilizers, analgesic agents, and diuretic medications that cause potassium loss). Table 39-3 presents the stages of hepatic encephalopathy, common signs and symptoms, and potential nursing diagnoses for each stage.

Clinical Manifestations
The earliest symptoms of hepatic encephalopathy include minor mental changes and motor disturbances. The patient appears slightly confused, has alterations in mood, becomes unkempt, and has altered sleep patterns. The patient tends to sleep during the day and have restlessness and insomnia at night. As hepatic encephalopathy progresses, the patient may be difficult to awaken.

Asterixis (flapping tremor of the hands) may occur (Fig. 39-12). Simple tasks, such as handwriting, become difficult. A handwriting or drawing sample (eg, star figure), taken daily, may provide graphic evidence of progression or reversal of hepatic encephalopathy. Inability to reproduce a simple figure (Fig. 39-13) is referred to as constructional apraxia. In the early stages of hepatic encephalopathy, the deep tendon reflexes are hyperactive; with worsening of hepatic encephalopathy, these reflexes disappear and the extremities may become flaccid.

Assessment and Diagnostic Findings
The electroencephalogram (EEG) shows generalized slowing, an increase in the amplitude of brain waves, and characteristic triphasic waves. Occasionally, fetor hepaticus, a sweet, slightly fecal odor to the breath presumed to be of intestinal origin may be noticed. The odor has also been described as similar to that of freshly mowed grass, acetone, or old wine. Fetor hepaticus is prevalent with extensive collateral portal circulation in chronic liver disease. In a more advanced stage, there are gross disturbances of consciousness and the patient is completely disoriented with respect to time and place. With further progression of the disorder, the patient lapses into frank coma and may have seizures. Approximately 35% of all patients with cirrhosis of the liver die in hepatic coma.

Medical Management
Lactulose (Cephulac) is administered to reduce serum ammonia levels. It acts by several mechanisms that promote the excretion of ammonia in the stool: (1) ammonia is kept in the ionized state, resulting in a fall in colon pH, reversing the normal passage of ammonia from the colon to the blood; (2) evacuation of the bowel takes place, which decreases the ammonia

| 2     | Increased drowsiness; disorientation; inappropriate behavior; mood swings; agitation | Asterixis; fetor hepaticus. Abnormal EEG with generalized slowing. | Impaired social interaction  
Ineffective role performance  
Risk for injury |
| 3     | Stuporous; difficult to rouse; sleeps most of time; marked confusion; incoherent speech | Asterixis; increased deep tendon reflexes; rigidity of extremities. EEG markedly abnormal. | Imbalanced nutrition  
Impaired mobility  
Impaired verbal communication |
| 4     | Comatose; may not respond to painful stimuli | Absence of asterixis; absence of deep tendon reflexes; flaccidity of extremities. EEG markedly abnormal. | Risk for aspiration  
Impaired gas exchange  
Impaired tissue integrity  
Disturbed sensory perception |

*Nursing diagnoses are likely to progress, so that most nursing diagnoses present at earlier stages will occur during later stages as well.*
to which some patients object, lactulose can be diluted with fruit juice. The patient is closely monitored for hypokalemia and dehydration. Other laxatives are not prescribed during lactulose administration because their effects would disturb dosage regulation. Lactulose can be administered by nasogastric tube or enema for patients who are comatose or in whom oral administration is contraindicated or impossible.

Other aspects of management include intravenous administration of glucose to minimize protein breakdown, administration of vitamins to correct deficiencies, and correction of electrolyte imbalances (especially potassium). Additional principles of management of hepatic encephalopathy include the following:

- Therapy is directed toward treating or removing the cause.
- Neurologic status is assessed frequently. A daily record is kept of handwriting and performance in arithmetic to monitor mental status.
- Fluid intake and output and body weight are recorded each day.
- Vital signs are measured and recorded every 4 hours.
- Potential sites of infection (peritoneum, lungs) are assessed frequently, and abnormal findings are reported promptly.
- Serum ammonia level is monitored daily.
- Protein intake is restricted in patients who are comatose or who have encephalopathy that is refractory to lactulose and antibiotic therapy (Chart 39-4).
- Reduction in the absorption of ammonia from the GI tract is accomplished by the use of gastric suction, enemas, or oral antibiotics.
- Electrolyte status is monitored and corrected if abnormal.
- Sedatives, tranquilizers, and analgesic medications are discontinued.
- Benzodiazepine antagonists (flumazenil [Romazicon]) may be administered to improve encephalopathy whether or not the patient has previously taken benzodiazepines.

**Nursing Management**

The nurse is responsible for maintaining a safe environment to prevent injury, bleeding, and infection. The nurse administers the prescribed treatments and monitors the patient for the many potential complications. The nurse also communicates with the pa-

---

**NURSING ALERT** The patient receiving lactulose is monitored closely for the development of watery diarrheal stools, because they indicate a medication overdose.

Possible side effects include intestinal bloating and cramps, which usually disappear within a week. To mask the sweet taste,
tient’s family to keep them informed about the patient’s status, and supports them by explaining the procedures and treatments that are part of the patient’s care. If the patient recovers from hepatic encephalopathy and coma, rehabilitation is likely to be prolonged. Thus, the patient and family will require assistance to understand the causes of this severe complication and to recognize that it may recur.

PROMOTING HOME AND COMMUNITY-BASED CARE

Teaching Patients Self-Care. If the patient has recovered from hepatic encephalopathy and is to be discharged home, the nurse instructs the family to watch for subtle signs of recurrent encephalopathy. In the acute phase of hepatic encephalopathy, dietary protein may be reduced to 0.8 to 1.0 g/kg per day. During recovery, and in the home situation, it is important to instruct the patient in maintenance of a low-protein, high-calorie diet. Protein may then be added in 10-g increments every 3 to 5 days. Any relapse is treated by a return to the previous level. The limits of tolerance are usually 40 to 60 g/day (1.0 to 1.5 g/kg per day). Continued use of lactulose in the home environment is not uncommon, and the patient and family should monitor its efficacy and side effects closely. Use of vegetable rather than animal protein may be indicated in patients whose total daily protein tolerance is less than 1 g/kg. Vegetable protein intake may result in improved nitrogen balance without precipitating or advancing hepatic encephalopathy (Menon & Kamath, 2000; Seymour & Whelan, 1999).

Continuing Care. Referral for home care is warranted for the patient who returns home after recovery from hepatic encephalopathy. The home care nurse assesses the patient’s physical and mental status and collaborates closely with the physician. The home visit also provides an opportunity for the nurse to assess the home environment and the ability of the patient and family to monitor signs and symptoms and to follow the treatment regimen. Home care visits are particularly important if the patient lives alone, because encephalopathy may affect the patient’s ability to remember or follow the treatment regimen. The nurse reinforces previous teaching and reminds the patient and family about the importance of dietary restrictions, close monitoring, and follow-up.

OTHER MANIFESTATIONS OF LIVER DYSFUNCTION

Edema and Bleeding

Many patients with liver dysfunction develop generalized edema from hypoalbuminemia that results from decreased hepatic production of albumin. The production of blood clotting factors by the liver is also reduced, leading to an increased incidence of bruising, epistaxis, bleeding from wounds, and, as described above, GI bleeding.

Vitamin Deficiency

Decreased production of several clotting factors may be due, in part, to deficient absorption of vitamin K from the GI tract. This probably is caused by the inability of liver cells to use vitamin K to make prothrombin. Absorption of the other fat-soluble vitamins (vitamins A, D, and E) as well as dietary fats may also be impaired because of decreased secretion of bile salts into the intestine.

Another group of problems common to patients with severe chronic liver dysfunction results from inadequate intake of sufficient vitamins. Among the specific deficiency states that occur on this basis are:

- Vitamin A deficiency, resulting in night blindness and eye and skin changes
- Thiamine deficiency, leading to beriberi, polyneuritis, and Wernicke-Korsakoff psychosis
- Riboflavin deficiency, resulting in characteristic skin and mucous membrane lesions
- Pyridoxine deficiency, resulting in skin and mucous membrane lesions and neurologic changes
- Vitamin C deficiency, resulting in the hemorrhagic lesions of scurvy
- Vitamin K deficiency, resulting in hypoprothrombinemia, characterized by spontaneous bleeding and ecchymoses
- Folic acid deficiency, resulting in macrocytic anemia

The threat of these avitaminoses provides the rationale for supplementing the diet of every patient with chronic liver disease (especially if alcohol-related) with ample quantities of vitamins A, B complex, C, and K and folic acid.

Metabolic Abnormalities

Abnormalities of glucose metabolism also occur; the blood glucose level may be abnormally high shortly after a meal (a diabetic-type glucose tolerance test result), but hypoglycemia may occur during fasting because of decreased hepatic glycogen reserves and decreased gluconeogenesis. Because the ability to metabolize medications is decreased, medications must be used cautiously and usual medication dosages must be reduced for the patient with liver failure.

Many endocrine abnormalities also occur with liver dysfunction because the liver cannot metabolize hormones normally, including androgens or sex hormones. Gynecomastia, amenorrhea, testicular atrophy, loss of pubic hair in the male, and menstrual irregularities in the female and other disturbances of sexual function and sex characteristics are thought to result from failure of the damaged liver to inactivate estrogens normally.

Pruritus and Other Skin Changes

Patients with liver dysfunction resulting from biliary obstruction commonly develop severe itching (pruritus) due to retention of bile salts. Patients may develop vascular (or arterial) spider angiomas (Fig. 39-14) on the skin, generally above the waistline. These are numerous small vessels resembling a spider’s legs. These are most frequently associated with cirrhosis, especially in alcoholic liver disease. Patients may also develop reddened palms (“liver palms” or palmar erythema).

Management of Patients With Viral Hepatic Disorders

VIRAL HEPATITIS

Viral hepatitis is a systemic, viral infection in which necrosis and inflammation of liver cells produce a characteristic cluster of clinical, biochemical, and cellular changes. To date, five definitive
types of viral hepatitis have been identified: hepatitis A, B, C, D, and E. Hepatitis A and E are similar in mode of transmission (fecal–oral route), whereas hepatitis B, C, and D share many characteristics. Terms associated with viral hepatitis are listed in Chart 39-5. The increasing incidence of viral hepatitis is a public health concern. The disease is important because it is easy to transmit, has high morbidity, and causes prolonged loss of time from school or employment.

It is estimated that 60% to 90% of cases of viral hepatitis go unreported. The occurrence of subclinical cases, failure to recognize mild cases, and misdiagnosis are thought to contribute to the underreporting. Although approximately 40% of all persons in the United States have antibodies against hepatitis A virus, many cannot recall an earlier episode or the occurrence of the symptoms of hepatitis (O’Grady et al., 2000). Table 39-4 compares the major forms of viral hepatitis.

**HEPATITIS A VIRUS (HAV)**

HAV accounts for 20% to 25% of cases of clinical hepatitis in the developed world. Hepatitis A, formerly called infectious hepatitis, is caused by an RNA virus of the Enterovirus family. The mode of transmission of this disease is the fecal–oral route, primarily through the ingestion of food or liquids infected by the virus. The virus has been found in the stool of infected patients before the onset of symptoms and during the first few days of illness. Typically, a child or a young adult acquires the infection at school by poor hygiene, hand-to-mouth contact, or close contact at play. The virus is carried home, where haphazard sanitary habits spread it through the family. It is more prevalent in developing countries or in areas with overcrowding and poor sanitation. An infected food handler can spread the disease, and people can contract it by consuming water or shellfish from sewage-contaminated waters. Outbreaks have occurred in day care centers and institutions for the developmentally delayed because of lapses in hygiene. It is rarely, if ever, transmitted by blood transfusions. Hepatitis A can be transmitted during sexual activity; this is more likely with

![Spider angioma. This vascular (arterial) spider appears on the skin. Beneath the elevated center and radiating branches, the blood vessels are looped and tortuous.](image)

oral–anal contact, anal intercourse, and a greater number of sex partners (CDC, 2002).

The incubation period is estimated to be 15 to 50 days, with an average of 30 days (O’Grady et al., 2000). The illness may be prolonged, lasting 4 to 8 weeks. It generally lasts longer and is more severe in those older than 40 years of age. Recovery is the rule; hepatitis A rarely progresses to acute liver necrosis or fulminating hepatitis, terminating in cirrhosis of the liver or death. Hepatitis A confers immunity against itself, but the person may contract other forms of hepatitis. The mortality rate of hepatitis A is approximately 0.5% for those under 40 years of age and increases to 1% to 2% for those over 40. No carrier state exists, and no chronic hepatitis is associated with hepatitis A. The virus is present only briefly in the serum; by the time jaundice occurs, the patient is likely to be noninfectious (O’Grady et al., 2000).

**Clinical Manifestations**

Many patients are anicteric (without jaundice) and symptomless. When symptoms appear, they are of a mild, flu-like upper respiratory tract infection, with low-grade fever. Anorexia, an early symptom, is often severe. It is thought to result from release of a toxin by the damaged liver or by failure of the damaged liver cells to detoxify an abnormal product. Later, jaundice and dark urine may become apparent. Indigestion is present in varying degrees, marked by vague epigastric distress, nausea, heartburn, and flatulence. The patient may also develop a strong aversion to the taste

of cigarettes or the presence of cigarette smoke and other strong odors. These symptoms tend to clear as soon as the jaundice reaches its peak, perhaps 10 days after its initial appearance. Symptoms may be mild in children; in adults, the symptoms may be more severe and the course of the disease prolonged.

Assessment and Diagnostic Findings

The liver and spleen are often moderately enlarged for a few days after onset; otherwise, apart from jaundice, there are few physical signs. Hepatitis A antigen may be found in the stool a week to 10 days before illness and for 2 to 3 weeks after symptoms appear. HAV antibodies are detectable in the serum, but usually not until symptoms appear. Analysis of subclasses of immunoglobulins can help determine whether the antibody represents acute or past infection.

Prevention

A number of strategies exist to prevent transmission of HAV. Patients and their families need to be made aware of these and encouraged to consider them if recommended by their primary health care provider.

In February 1995, the Food and Drug Administration approved the first vaccine against hepatitis A for use in the United States. Effective and safe HAV vaccines include Havrix and Vaxiguard (Koff, 2001). It is recommended that the two-dose vaccine be given to adults 18 years of age or older, with the second dose 6 to 12 months after the first. Protection against hepatitis A develops within several weeks after the first dose of the vaccine. Children and adolescents 2 to 18 years of age receive three doses, with the second dose 1 month after the first and the third dose 6 to 12 months later. It is estimated that protection against hepatitis A may last for at least 20 years (CDC, 1999). No country has as yet recommended universal vaccination against hepatitis A. Hepatitis A vaccine is recommended for travelers to locations where sanitation and hygiene are unsatisfactory. Vaccination is also recommended for those from other high-risk groups (homosexual men, injection/intravenous drug users, staff of day care centers, and health care personnel) (CDC, 2002). The vaccine has also been used to interrupt community-wide outbreaks. As with other vaccinations, precautions must be taken to ensure prevention, detection, and treatment of hypersensitivity reactions to the vaccine.

Type A hepatitis can be prevented in those not previously vaccinated by the intramuscular administration of globulin during the incubation period, if given within 2 weeks of exposure. This bolsters the person’s antibody production and provides 6 to 8 weeks of passive immunity. Immune globulin may suppress overt symptoms of the disease; the resulting subclinical case of hepatitis A would produce active immunity to subsequent episodes of the virus.

Immune globulin is also recommended for household members and sexual contacts of people with hepatitis A. Susceptible people in the same household as the patient are usually also infected by the time the diagnosis is made and should receive immune globulin. Day care center and restaurant workers with exposure to or infected with hepatitis A should also receive immune globulin to provide passive immunity (CDC, 1999). Although rare, systemic reactions to immune globulin may occur. Caution is required when anyone who has previously had angioedema, hives, or other allergic reactions is treated with any human immune globulin. Epinephrine should be available in case a systemic, anaphylactic reaction occurs.

Preexposure prophylaxis is recommended for those traveling to developing countries and settings with poor or uncertain sanitation conditions but who do not have sufficient time to acquire protection by administration of hepatitis A vaccine (CDC, 1999). Community interventions for preventing hepatitis A are outlined in Chart 39-6.

Medical Management

Bed rest during the acute stage and a diet that is both acceptable to the patient and nutritious are part of the treatment and nursing care. During the period of anorexia, the patient should receive frequent small feedings, supplemented, if necessary, by IV fluids with glucose. Because this patient often has an aversion to food, gentle persistence and creativity may be required to stimulate the appetite. Optimal food and fluid levels are necessary to counteract weight loss and slow recovery. Even before the icteric phase, however, many patients recover their appetites (Chart 39-7).

The patient’s sense of well-being as well as laboratory test results are generally appropriate guides to bed rest and restriction of physical activity. Gradual but progressive ambulation seems to hasten recovery, provided the patient rests after activity and does not participate in activities to the point of fatigue.

Nursing Management

The patient is usually managed at home unless symptoms are severe. Therefore, the nurse assists the patient and family in coping with the temporary disability and fatigue that are common in hepatitis and instructs them to seek additional health care if the
HEPATITIS B VIRUS (HBV)

Unlike hepatitis A, which is transmitted primarily by the fecal–oral route, hepatitis B is transmitted primarily through blood (percutaneous and permucosal routes). HBV has been found in blood, saliva, semen, and vaginal secretions and can be transmitted through mucous membranes and breaks in the skin. HBV is also transferred from carrier mothers to their babies, especially in areas with a high incidence (ie, Southeast Asia). The infection is usually not via the umbilical vein, but from the mother at the time of birth and during close contact afterward.

HBV has a long incubation period. It replicates in the liver and remains in the serum for relatively long periods, allowing transmission of the virus. Those at risk for developing hepatitis B include surgeons, clinical laboratory workers, dentists, nurses, and respiratory therapists. Staff and patients in hemodialysis and oncology units and sexually active homosexual and bisexual men and injection drug users are also at increased risk. Screening of blood donors has greatly reduced the occurrence of hepatitis B after blood transfusion.

Most people (>90%) who contract hepatitis B infections will develop antibodies and recover spontaneously in 6 months. The mortality rate from hepatitis B has been reported to be as high as 10%. Another 10% of patients who have hepatitis B progress to mortality rate from hepatitis B has been reported to be as high as 10%. Another 10% of patients who have hepatitis B progress to chronic hepatitis with persistent HBV infection. Chronic HBV infection can lead to liver fibrosis, cirrhosis, and hepatocellular carcinoma as a major cause of cirrhosis and hepatocellular carcinoma worldwide.

Nursing Alert The Food and Drug Administration (CDC, 2001) has approved a combined hepatitis A and B vaccine (Twinrix) for vaccination of persons 18 years of age and older with indications for both hepatitis A and B vaccination. Vaccination consists of three doses, on the same schedule as that used for single-antigen hepatitis B vaccine.

Clinical Manifestations

Clinically, the disease closely resembles hepatitis A, but the incubation period is much longer (1 to 6 months). Signs and symptoms of hepatitis B may be insidious and variable. Fever and respiratory symptoms are rare; some patients have arthralgias and rashes. The patient may have loss of appetite, dyspepsia, abdominal pain, generalized aching, malaise, and weakness. Jaundice may or may not be evident. If jaundice occurs, light-colored stools and dark urine accompany it. The liver may be tender and enlarged to 12 to 14 cm vertically. The spleen is enlarged and palpable in a few patients; the posterior cervical lymph nodes may also be enlarged. Subclinical episodes also occur frequently.

Assessment and Diagnostic Findings

HBV is a DNA virus composed of the following antigenic particles:

- HBcAg—hepatitis B core antigen (antigenic material in an inner core)
- HBsAg—hepatitis B surface antigen (antigenic material on surface of HBV)
- HBeAg—an independent protein circulating in the blood
- HBxAg—gene product of X gene of HBV/DNA

Each antigen elicits its specific antibody and is a marker for different stages of the disease process:

- anti-HBc—antibody to core antigen or HBV; persists during the acute phase of illness; may indicate continuing HBV in the liver
- anti-HBs—antibody to surface determinants on HBV; detected during late convalescence; usually indicates recovery and development of immunity
- anti-HBc—antibody to hepatitis B e-antigen; usually signifies reduced infectivity
- anti-HBxAg—antibody to the hepatitis B x-antigen; may indicate ongoing replication of HBV

HBsAg appears in the circulation in 80% to 90% of infected patients 1 to 10 weeks after exposure to HBV and 2 to 8 weeks before the onset of symptoms or an increase in transaminase (transaminase) levels. Patients with HBsAg that persists for 6 or more months after acute infection are considered HBsAg carriers (Befeler & Di Bisceglie, 2000). HBeAg is the next antigen of HBV to appear in the serum. It usually appears within a week of the appearance of HBsAg and before changes in aminotransferase levels, disappearing from the serum within 2 weeks. HBV DNA, detected by polymerase chain reaction testing, appears in the serum at about the same time as HBeAg. HBcAg is not always detected in the serum in HBV infection.

About 15% of American adults are positive for anti-HBs, which indicates that they have had hepatitis B. Anti-HBs may be positive in as many as two thirds of IV/injection drug users.

Prevention

The goals of prevention are to interrupt the chain of transmission, to protect people at high risk with active immunization through the use of hepatitis B vaccine, and to use passive immunization for unprotected people exposed to HBV.

Preventing Transmission

Continued screening of blood donors for the presence of hepatitis B antigens will further decrease the risk of transmission by

Risk Factors for Hepatitis B

- Frequent exposure to blood, blood products, or other body fluids
- Health care workers: hemodialysis staff, oncology and chemotherapy nurses, personnel at risk for needlesticks, operating room staff, respiratory therapists, surgeons, dentists
- Hemodialysis
- Male homosexual and bisexual activity
- IV/injection drug use
- Close contact with carrier of HBV
- Travel to or residence in area with uncertain sanitary conditions
- Multiple sexual partners
- Recent history of sexually transmitted disease
- Receipt of blood or blood products (eg, clotting factor concentrate)
blood transfusion. The use of disposable syringes, needles, and lancets and the introduction of needleless IV administration systems reduce the risk of spreading this infection from one patient to another or to health care personnel during the collection of blood samples or the administration of parenteral therapy. Good personal hygiene is fundamental to infection control. In the clinical laboratory, work areas should be disinfected daily. Gloves are worn when handling all blood and body fluids as well as HBAg-positive specimens, or when there is potential exposure to blood (blood drawing) or to patients’ secretions. Eating and smoking are prohibited in the laboratory and in other areas exposed to secretions, blood, or blood products. Patient education regarding the nature of the disease, its infectiousness, and prognosis is a critical factor in preventing transmission and protecting contacts.

**ACTIVE IMMUNIZATION: HEPATITIS B VACCINE**

Active immunization is recommended for individuals at high risk for hepatitis B (eg, health care personnel and hemodialysis patients). In addition, individuals with hepatitis C and other chronic liver diseases should receive the vaccine (CDC, 1999). A yeast-recombinant hepatitis B vaccine (Recombivax HB) is used to provide active immunity. Long-term studies of healthy adults and children indicate that immunologic memory remains intact for at least 5 to 10 years, although antibody levels may become low or undetectable. Measurable levels of antibodies may not be essential for protection. In those with normal immune systems, booster doses are not generally required. The CDC (2002) does not recommend booster doses at this time except for hemodialysis patients. The need for booster doses may be revisited if reports of hepatitis B increase or an increased prevalence of the carrier state develops, indicating that protection is declining.

A hepatitis B vaccine prepared from plasma of humans chronically infected with HBV is used only rarely and in patients who are immunodeficient or allergic to recombinant yeast-derived vaccines.

Both forms of the hepatitis B vaccine are administered intramuscularly in three doses, the second and third doses 1 and 6 months after the first dose. The third dose is very important in producing prolonged immunity. Hepatitis B vaccination should be administered to adults in the deltoid muscle. Antibody response may be measured by anti-HBs levels 1 to 3 months after completing the basic course of vaccine, but this testing is not routine and not currently recommended. Individuals who fail to respond may benefit from one to three additional doses (Koff, 2001).

People at high risk, including nurses and other health care personnel exposed to blood or blood products, should receive active immunization. Health care workers who have had frequent contact with blood are screened for anti-HBs to determine whether immunity is already present from previous exposure. The vaccine produces active immunity to HBV in 90% of healthy people (Koff, 2001). It does not provide protection to those already exposed to HBV and provides no protection against other types of viral hepatitis. Side effects of immunization are infrequent; soreness and redness at the injection site are the most common complaints.

Because hepatitis B infection is frequently transmitted sexually, hepatitis B vaccination is recommended for all unvaccinated persons being evaluated for a sexually transmitted disease (STD). It is also recommended for those with a history of an STD, persons with multiple sex partners, those who have sex with injection drug users, and sexually active men who have sex with other men (CDC, 2002).

Universal childhood vaccination for hepatitis B prevention has been instituted in the United States. Vaccination was initially targeted for select high-risk populations, but the U.S. Public Health Service and the CDC (1999) have endorsed universal vaccination of all infants. Catch-up vaccination is also recommended for all children and adolescents up to the age of 19 who were not previously immunized. Studies (Chang, 2000; Wu et al., 1999) show that universal vaccination of all newborns in endemic areas has dramatically reduced the carrier rate among children and the incidence of childhood hepatocellular carcinoma. In the United States, studies regarding the effectiveness of the vaccine are ongoing, but it is known that clinical infection is rarely observed during long-term follow-up of known responders (ie, health care workers) who seroconverted within 3 months of the third dose of vaccine (Bircher et al., 1999). Development of chronic carrier states has not been reported in adult responders to the vaccine.

**PASSIVE IMMUNITY: HEPATITIS B IMMUNE GLOBULIN**

Hepatitis B immune globulin (HBIG) provides passive immunity to hepatitis B and is indicated for people exposed to HBV who have never had hepatitis B and have never received hepatitis B vaccine. Specific indications for postexposure vaccine with HBIG include: (1) inadvertent exposure to HBAg-positive blood through percutaneous (needlestick) or transmucosal (spashes in contact with mucous membrane) routes, (2) sexual contact with people positive for HBAg, and (3) perinatal exposure (babies born to HBV-infected mothers should receive HBIG within 12 hours of delivery). HBIG, which provides passive immunity, is prepared from plasma selected for high titers of anti-HBs. Prompt immunization with HBIG (within hours to a few days after exposure to hepatitis B) increases the likelihood of protection. Both active and passive immunization are recommended for people exposed to hepatitis B through sexual contact or through percutaneous or transmucosal routes. If HBIG and hepatitis B vaccine are administered at the same time, separate sites and separate syringes should be used. Prophylaxis with high doses of HBIG started at the time of liver transplantation and continued indefinitely improves survival by thwarting recurrence of hepatitis B (Bacon & Di Bisceglie, 2000). There has been no evidence that HIV infection can be transmitted by HBIG.

**Gerontologic Considerations**

The elderly patient who contracts hepatitis B has a serious risk of severe liver cell necrosis or fulminant hepatic failure, particularly if other illnesses are present. The patient is seriously ill and the prognosis is poor, so efforts should be undertaken to eliminate other factors (eg, medications, alcohol) that may affect liver function.

**Medical Management**

The goals of treatment are to minimize infectivity, normalize liver inflammation, and decrease symptoms. Of all the agents that have been used to treat chronic type B viral hepatitis, alpha interferon as the single modality of therapy offers the most promise. This regimen of 5 million units daily or 10 million units three times weekly for 4 to 6 months results in remission of disease in approximately one third of patients (Befeler & Di Bisceglie, 2000). The long-term benefits of this treatment are being assessed. Interferon must be administered by injection and has significant side effects, including fever, chills, anorexia, nausea, myalgias, and fatigue. Late side effects are more serious and may necessitate dosage reduction or discontinuation. These include bone marrow suppression, thyroid dysfunction, alopecia, and bacterial infections.

Two antiviral agents (lamivudine [Epivir] and adefovir [Hepsera]) oral nucleoside analogs, have been approved for use in
chronic hepatitis B in the United States. Viral resistance may be an issue with these agents, and studies of their effectiveness alone and in combination with other therapies are ongoing (Befeler & Di Bisceglie, 2000).

Bed rest may be recommended, regardless of other treatment, until the symptoms of hepatitis have subsided. Activities are restricted until the hepatic enlargement and elevated levels of serum bilirubin and liver enzymes have disappeared. Gradually increased activity is then allowed.

Adequate nutrition should be maintained; proteins are restricted when the liver’s ability to metabolize protein byproducts is impaired, as demonstrated by symptoms. Measures to control the dyspeptic symptoms and general malaise include the use of antacids and antiemetics, but all medications should be avoided if vomiting occurs. If vomiting persists, the patient may require hospitalization and fluid therapy. Because of the mode of transmission, the patient is evaluated for other bloodborne diseases (e.g., HIV infection).

Nursing Management

Convalescence may be prolonged, with complete symptomatic recovery sometimes requiring 3 to 4 months or longer. During this stage, gradual resumption of physical activity is encouraged after the jaundice has resolved.

The nurse identifies psychosocial issues and concerns, particularly the effects of separation from family and friends if the patient is hospitalized during the acute and infective stages. Even if not hospitalized, the patient will be unable to work and must avoid sexual contact. Planning is required to minimize alterations in sensory perception. Planning that includes the family helps to decrease their fears and anxieties about the spread of the disease.

PROMOTING HOME AND COMMUNITY-BASED CARE

Teaching Patients Self-Care. Because of the prolonged period of convalescence, the patient and family must be prepared for home care. Provision for adequate rest and nutrition must be ensured. The nurse informs family members and friends who have had intimate contact with the patient about the risks of contracting hepatitis B and makes arrangements for them to receive hepatitis B vaccine or hepatitis B immune globulin as prescribed. Those at risk must be aware of the early signs of hepatitis B and of ways to reduce risk to themselves by avoiding all modes of transmission. Patients with all forms of hepatitis should avoid drinking alcohol.

Continuing Care. Follow-up visits by a home care nurse may be needed to assess the patient’s progress and answer family members’ questions about disease transmission. A home visit also permits assessment of the patient’s physical and psychological status and the patient and family’s understanding of the importance of adequate rest and nutrition. The nurse also reinforces previous instructions. Because of the risk of transmission through sexual intercourse, strategies to prevent exchange of body fluids are advised, such as abstinence or the use of condoms. The nurse emphasizes the importance of keeping follow-up appointments and participating in other health promotion activities and recommended health screenings.

HEPATITIS C VIRUS (HCV)

A significant proportion of cases of viral hepatitis are neither hepatitis A, hepatitis B, nor hepatitis D; as a result, they are classified as hepatitis C (formerly referred to as non-A, non-B hepatitis, or NANB hepatitis). Whereas blood transfusions and sexual contact once accounted for most cases of hepatitis C in the United States, other parenteral means, such as sharing contaminated needles by IV/injection drug users and unintentional needlesticks and other injuries in health care workers, now account for a significant number of cases. There are approximately 35,000 new cases of hepatitis C in the United States each year. About 4 million persons (1.8% of the U.S. population) have been infected with HCV, making it the most common chronic blood-borne infection nationally. A fourfold increase in the number of adults diagnosed with HCV is projected from 1990 to 2015. The highest prevalence of hepatitis C is in adults 40 to 59 years of age, and in this age group its prevalence is highest in African Americans. There are 10,000 to 12,000 deaths each year in the United States due to hepatitis C; it has been suggested that these are underestimates. HCV is the underlying cause of about one-third of cases of hepatocellular carcinoma, and it is the most common reason for liver transplantation (NIH Consensus Conference, 2002).

Individuals at special risk for hepatitis C include IV/injection drug users, sexually active people with multiple partners, patients receiving frequent transfusions or those who require large volumes of blood, and health care personnel. The incubation period is variable and may range from 15 to 160 days. The clinical course of acute hepatitis C is similar to that of hepatitis B; symptoms are usually mild. A chronic carrier state occurs frequently, however, and there is an increased risk of chronic liver disease, including cirrhosis or liver cancer, after hepatitis C. Small amounts of alcohol taken regularly appear to encourage progression of the disease. Therefore, alcohol and medications that may affect the liver should be avoided (Chart 39-9).

There is no benefit from rest, diet, or vitamin supplements. Recent studies have demonstrated that a combination of interferon (Intron-A) and ribavirin (Rebetol), two antiviral agents, is effective in producing improvement in patients with hepatitis C and in treating relapses. Some patients experience complete remission with combination therapy, which is the treatment of choice according to the FDA (Cheney, Chopra & Graham, 2000). Hepatitis C virus, the most frequent side effect, may be severe enough to require discontinuation of treatment. Ribavirin must be used with caution in women of childbearing age. A molecule (polyethylene glycol moiety [PEG]) added to the interferon keeps it in the body longer without reducing its efficacy and extends the dosing interval to once a week. Pegylated interferon (Pegasys) is now available (Lauer & Walker, 2001; Sheffield et al., 2001).

Screening of blood has reduced the incidence of hepatitis associated with blood transfusions, and public health programs are helping to reduce the number of cases associated with shared needles in illicit drug use.

Chart 39-9

Risk Factors for Hepatitis C

- Recipient of blood products or organ transplant prior to 1992 or clotting factor concentrates before 1987
- Health care and public safety workers after needlestick injuries or mucosal exposure to blood
- Children born to women infected with hepatitis C virus
- Past/current illicit IV/injection drug use
- Past treatment with chronic hemodialysis
- Sex with infected partner, having multiple sex partners, history of STD, unprotected sex
**HEPATITIS D VIRUS (HDV)**

Hepatitis D (delta agent) occurs in some cases of hepatitis B. Because the virus requires hepatitis B surface antigen for its replication, only individuals with hepatitis B are at risk for hepatitis D. Anti-delta antibodies in the presence of HBAg on testing confirm the diagnosis. It is also common among IV/injection drug users, hemodialysis patients, and recipients of multiple blood transfusions. Sexual contact with those with hepatitis B is considered to be an important mode of transmission of hepatitis B and D. The incubation period varies between 21 and 140 days (Bacon & Di Bisceglie, 2000).

The symptoms of hepatitis D are similar to those of hepatitis B, except that patients are more likely to develop fulminant hepatitis and to progress to chronic active hepatitis and cirrhosis. Treatment is similar to that of other forms of hepatitis; interferon as a specific treatment for hepatitis D is under investigation.

**HEPATITIS E VIRUS (HEV)**

Hepatitis E is believed to be transmitted by the fecal–oral route, principally through contaminated water in areas with poor sanitation. The incubation period is variable, estimated to range between 15 and 65 days. In general, hepatitis E resembles hepatitis A. It has a self-limiting course with an abrupt onset. Jaundice is nearly always present. Chronic forms do not develop.

Avoiding contact with the virus through good hygiene, including hand washing, is the major method of prevention of hepatitis E. The effectiveness of immune globulin in protecting against hepatitis E virus is uncertain.

**HEPATITIS G (HGV) AND GB VIRUS-C**

It has long been believed that there is another non-A, non-B, non-C agent causing hepatitis in humans. The incubation period for post-transfusion hepatitis is 14 to 145 days, too long for hepatitis B or C. In the United States, about 5% of chronic liver disease remains cryptogenic (does not appear to be autoimmune or viral in origin), and half the patients have previously received transfusions. Thus, a new form of hepatitis (hepatitis G or GBV-C) has been described. They are two different isolates of the same virus. Autoantibodies are absent.

The clinical significance of this virus remains uncertain. Risk factors are similar to those for hepatitis C. There is no clear relationship between GBV-C/HGV infection and progressive liver disease. Persistent infection does occur but does not affect the clinical course.

**TOXIC HEPATITIS**

Toxic hepatitis resembles viral hepatitis in onset. Obtaining a history of exposure to hepatotoxic chemicals, medications, or other agents assists in early treatment and removal of the offending agent. Anorexia, nausea, and vomiting are the usual symptoms; jaundice and hepatomegaly are noted on physical assessment. Symptoms are more intense for the more severely toxic patient.

Recovery from acute toxic hepatitis is rapid if the hepatotoxin is identified early and removed or if exposure to the agent has been limited. Recovery is unlikely if there is a prolonged period between exposure and onset of symptoms. There are no effective antidotes. The fever rises; the patient becomes toxic and prostrated. Vomiting may be persistent, with the emesis containing blood. Clotting abnormalities may be severe, and hemorrhages may appear under the skin. The severe GI symptoms may lead to vascular collapse. Delirium, coma, and seizures develop, and within a few days the patient may die of fulminant hepatic failure (discussed below) unless he or she receives a liver transplant.

Short of liver transplantation, few treatment options are available. Therapy is directed toward restoring and maintaining fluid and electrolyte balance, blood replacement, and comfort and supportive measures. A few patients recover from acute toxic hepatitis only to develop chronic liver disease. If the liver heals, there may be scarring, followed by postnecrotic cirrhosis.

**DRUG-INDUCED HEPATITIS**

Drug-induced hepatitis is responsible for 20% to 25% of cases of acute liver failure in the United States (Maddrey, Schiff & Sorrell, 2001). Manifestations of sensitivity to a medication may occur on the first day of its use or not until several months later, depending on the medication. Usually the onset is abrupt, with chills, fever, rash, pruritus, arthralgia, anorexia, and nausea. Later, there may be jaundice and dark urine and an enlarged and tender liver. When the offending medication is withdrawn, symptoms may gradually subside. However, reactions may be severe and even fatal, even though the medication is stopped. If fever, rash, or pruritus occurs from any medication, its use should be stopped immediately.

Although any medication can affect liver function, use of acetaminophen (found in many over-the-counter medications used to treat fever and pain) has been identified as the leading cause of acute liver failure (Ostapowicz, Fontana, Schiodt, et al., 2002). Others commonly associated with liver injury include but are not limited to anesthetic agents, medications used to treat rheumatic and musculoskeletal disease, antidepressants, psychotropic medications, anticonvulsants, and anti-tuberculosis agents.

Inhalational agents of the halothane family (halokanes) are metabolized by the liver and excreted in bile. These volatile anesthetics may also decrease hepatic blood flow. Halothane hepatitis is a dreaded but rare complication of halothane administration. Sevoflurane and desflurane may have less hepatotoxic effects than halokanes. Nitrous oxide, an adjunct to halokanes, is not hepatotoxic. Because it undergoes little hepatic metabolism, isoflurane is considered the anesthetic agent of choice in patients with liver disease (Bacon & Di Bisceglie, 2000).

Although its efficacy is uncertain, a short course of high-dose corticosteroids may be used in patients with severe hypersensitivity. Liver transplantation is an option for drug-induced hepatitis, but outcomes may not be as successful as with other causes of liver failure.
FULMINANT HEPATIC FAILURE

Fulminant hepatic failure is the clinical syndrome of sudden and severely impaired liver function in a previously healthy person. According to the original and generally accepted definition, fulminant hepatic failure develops within 8 weeks of the first symptoms of jaundice (Maddrey et al., 2001). Patterns of the progression from jaundice to encephalopathy have been identified and have led to proposals of time-based classifications, but no agreement as to these classifications has been reached. However, three categories are frequently cited: hyperacute, acute, and subacute liver failure. In hyperacute liver failure, the duration of jaundice before the onset of encephalopathy is 0 to 7 days; in acute liver failure, it is 8 to 28 days; and in subacute liver failure, it is 28 to 72 days. The prognosis for fulminant hepatic failure is much worse than for chronic liver failure. However, in fulminant failure, the hepatic lesion is potentially reversible, with survival rates of approximately 50% to 85% (survival rates depend greatly on the etiology of liver failure). Those who do not survive die of massive hepatocellular injury and necrosis (Maddrey et al., 2001).

Viral hepatitis is a common cause of fulminant hepatic failure; other causes include toxic medications (eg, acetaminophen) and chemicals (eg, carbon tetrachloride), metabolic disturbances (Wilson’s disease, a hereditary syndrome with deposition of copper in the liver), and structural changes (Budd-Chiari syndrome, an obstruction to outflow in major hepatic veins).

Jaundice and profound anorexia may be the initial reasons the patient seeks health care. Fulminant hepatic failure is often accompanied by coagulation defects, renal failure and electrolyte disturbances, infection, hypoglycemia, encephalopathy, and cerebral edema.

Management

The key to optimizing treatment is rapid recognition of acute liver failure and intensive interventions. Treatment modalities may include plasma exchanges (plasmapheresis) or charcoal hemoperfusion for the removal (theoretically) of potentially harmful metabolites (Kaptanoglu & Blei, 2000); however, more clinical trials are needed to determine their effects or outcomes. Hepatocytes within synthetic fiber columns have been tested as liver support systems (liver assist devices) and a bridge to transplantation.

Research into interventions for acute liver failure has begun to focus on techniques that combine the efficacy of a whole liver, with the convenience and biocompatibility of hemodialysis. The acronyms ELAD (extracorporeal liver assist devices) and BAL (bioartificial liver) have been used to describe these hybrid devices. These temporary devices help patients to survive until transplantation is possible. The BAL exposes separated plasma to a cartridge containing porcine liver cells after the plasma has flowed through a charcoal column that removes substances toxic to hepatocytes. The ELAD device exposes whole blood to cartridges containing porcine liver cells after the plasma has flowed through a charcoal column that removes substances toxic to hepatocytes.

Careful fluid balance and hemodynamic assessments, a quiet environment, and diuresis with mannitol, an osmotic diuretic.

To prevent surges in intracranial pressure related to agitation, barbiturate anesthesia or pharmacologic paralysis and sedation are indicated. Other support measures include monitoring for and treating hypoglycemia, coagulopathies, and infection. Despite these treatment modalities, the mortality rate remains high. Consequently, liver transplantation (discussed later in this chapter) has become the treatment of choice for fulminant hepatic failure.

HEPATIC CIRRHOSIS

Cirrhosis is a chronic disease characterized by replacement of normal liver tissue with diffuse fibrosis that disrupts the structure and function of the liver. There are three types of cirrhosis or scarring of the liver:

- Alcohol cirrhosis, in which the scar tissue characteristics surrounds the portal areas. This is most frequently due to chronic alcoholism and is the most common type of cirrhosis.
- Postnecrotic cirrhosis, in which there are broad bands of scar tissue as a late result of a previous bout of acute viral hepatitis.
- Biliary cirrhosis, in which scarring occurs in the liver around the bile ducts. This type usually is the result of chronic biliary obstruction and infection (cholangitis); it is much less common than the other two types.

The portion of the liver chiefly involved in cirrhosis consists of the portal and the periportal spaces, where the bile canaliculi of each lobule communicate to form the liver bile ducts. These areas become the sites of inflammation, and the bile ducts become occluded with inspissated (thickened) bile and pus. The liver attempts to form new bile channels; hence, there is an overgrowth of tissue made up largely of disconnected, newly formed bile ducts and surrounded by scar tissue.

Clinical manifestations include intermittent jaundice and fever. Initially the liver is enlarged, hard, and irregular, but eventually it atrophies.

Pathophysiology

Although several factors have been implicated in the etiology of cirrhosis, alcohol consumption is considered the major causative factor. Cirrhosis occurs with greatest frequency among alcoholics. Although nutritional deficiency with reduced protein intake contributes to liver destruction in cirrhosis, excessive alcohol intake is the major causative factor in fatty liver and its consequences. Cirrhosis, however, has also occurred in people who do not consume alcohol and in those who consume a normal diet and have a high alcohol intake.

Some people appear to be more susceptible than others to this disease, whether or not they are alcoholics or malnourished. Other factors may play a role, including exposure to certain chemicals (carbon tetrachloride, chlorinated naphthalene, arsenic, or phosphorus) or infectious schistosomiasis. Twice as many men as women are affected, although women are at greater risk of developing alcohol-induced liver disease for an as yet undiscovered reason. Most patients are between 40 and 60 years of age. Each year more than 25,000 people die of chronic liver diseases and cirrhosis in the United States (NIDDK, 2000).

Alcoholic cirrhosis is characterized by episodes of necrosis involving the liver cells, sometimes occurring repeatedly throughout...
the course of the disease. The destroyed liver cells are replaced gradually by scar tissue; eventually the amount of scar tissue exceeds that of the functioning liver tissue. Islands of residual normal tissue and regenerating liver tissue may project from the constricted areas, giving the cirrhotic liver its characteristic hobnail appearance. The disease usually has an insidious onset and a protracted course, occasionally proceeding over a period of 30 or more years.

The prognosis of different forms of cirrhosis caused by various liver diseases has been investigated in several studies. Of the many prognostic indicators, the Child’s classification seems most useful in predicting the outcome of patients with liver disease (Table 39-5). It is also used in choosing management approaches.

Clinical Manifestations

Signs and symptoms of cirrhosis increase in severity as the disease progresses. The severity of the manifestations helps to categorize the disorder into two main presentations (Chart 39-10).

Compensated cirrhosis, with its less severe, often vague symptoms, may be discovered secondarily at a routine physical examination. The hallmarks of decompensated cirrhosis result from failure of the liver to synthesize proteins, clotting factors, and other substances and manifestations of portal hypertension (see the “Hepatic Dysfunction” section of this chapter for clinical manifestations and management of portal hypertension, ascites, varices, and hepatic encephalopathy).

LIVER ENLARGEMENT

Early in the course of cirrhosis, the liver tends to be large and its cells loaded with fat. The liver is firm and has a sharp edge noticeable on palpation. Abdominal pain may be present because of recent, rapid enlargement of the liver, producing tension on the fibrous covering of the liver (Glisson’s capsule). Later in the disease, the liver decreases in size as scar tissue contracts the liver tissue. The liver edge, if palpable, is nodular.

PORTAL OBSTRUCTION AND ASCITES

These late manifestations are due partly to chronic failure of liver function and partly to obstruction of the portal circulation. Practically all the blood from the digestive organs is collected in the portal veins and carried to the liver. Because a cirrhotic liver does not allow the blood free passage, it backs up into the spleen and the GI tract and these organs become the seat of chronic passive congestion; that is, they are stagnant with blood and thus cannot function properly. Indigestion and altered bowel function result. Fluid rich in protein may accumulate in the peritoneal cavity, producing ascites. This can be demonstrated through percussion for shifting dullness or a fluid wave (see Fig. 39-5).

INFECTION AND PERITONITIS

Bacterial peritonitis may develop in cirrhotic patients with ascites in the absence of an intra-abdominal source of infection or an abscess. This condition is referred to as spontaneous bacterial peritonitis. Bacteremia is believed to be the most likely route of infection. Clinical signs may be absent; paracentesis may be necessary for diagnosis. Antibiotic therapy is effective in the treatment and prevention of recurrent episodes of spontaneous bacterial peritonitis.

GASTROINTESTINAL VARICES

The obstruction to blood flow through the liver resulting from the fibrotic changes also results in the formation of collateral blood vessels in the GI system and shunting of blood from the portal vessels into blood vessels with lower pressures. As a result, the patient with cirrhosis often has prominent, distended abdominal blood vessels, which are visible on abdominal inspection (caput medusae), and
distended blood vessels throughout the GI tract. The esophagus, stomach, and lower rectum are common sites of collateral blood vessels. These distended blood vessels form varices or hemorrhoids, depending on their location (see Fig. 39-6).

Because these vessels were not intended to carry the high pressure and volume of blood imposed by cirrhosis, they may rupture and bleed. Therefore, assessment must include observation for occult and frank bleeding from the GI tract. Approximately 25% of patients develop minor hematomas; others have profuse hemorrhage from gastric and esophageal varices (Bacon & Di Bisceglie, 2000).

**EDEMA**

Another late symptom of cirrhosis is edema, which is attributed to chronic liver failure. A reduced plasma albumin concentration predisposes the patient to the formation of edema. Edema is generalized but often affects lower extremities, upper extremities, and the presacral area. Facial edema is not typical. Overproduction of aldosterone occurs, causing sodium and water retention and potassium excretion.

**VITAMIN DEFICIENCY AND ANEMIA**

Because of inadequate formation, use, and storage of certain vitamins (notably vitamins A, C, and K), signs of their deficiency are common, particularly hemorrhagic phenomena associated with vitamin K deficiency. Chronic gastritis and impaired GI function, together with inadequate dietary intake and impaired liver function, account for the anemia often associated with cirrhosis. The anemia and the patient’s poor nutritional status and poor state of health result in severe fatigue, which interferes with the ability to carry out routine daily activities.

**MENTAL DETERIORATION**

Additional clinical manifestations include deterioration of mental function with impending hepatic encephalopathy and hepatic coma. Neurologic assessment is indicated and includes the patient’s general behavior, cognitive abilities, orientation to time and place, and speech patterns.

**Assessment and Diagnostic Findings**

The extent of liver disease and the type of treatment are determined after reviewing the laboratory findings. Because the functions of the liver are complex, there are many diagnostic tests that may provide information about liver function (see Table 39-1). The patient needs to know why these tests are being performed and ways to cooperate.

In severe parenchymal liver dysfunction, the serum albumin level tends to decrease and the serum globulin level rises. Enzyme tests indicate liver cell damage: serum alkaline phosphatase, AST, ALT, and GGT levels increase, and the serum cholinesterase level may decrease. Bilirubin tests are performed to measure bile excretion or bile retention; elevated levels can occur with cirrhosis and other liver disorders. Prothrombin time is prolonged.

Ultrasound scanning is used to measure the difference in density of parenchymal cells and scar tissue. CT, MRI, and radionuclide liver scans give information about liver size and hepatic blood flow and obstruction. Diagnosis is confirmed by liver biopsy. Arterial blood gas analysis may reveal a ventilation-perfusion imbalance and hypoxia.

**Medical Management**

The management of the patient with cirrhosis is usually based on the presenting symptoms. For example, antacids are prescribed to decrease gastric distress and minimize the possibility of GI bleeding. Vitamins and nutritional supplements promote healing of damaged liver cells and improve the general nutritional status. Potassium-sparing diuretics (spironolactone [Aldactone], triamterene [Dyrenium]) may be indicated to decrease ascites, if present; these diuretics are preferable to other diuretic agents because they minimize the fluid and electrolyte changes common with other agents. An adequate diet and avoidance of alcohol are essential. Although the fibrosis of the cirrhotic liver cannot be reversed, its progression may be halted or slowed by such measures.

Preliminary studies indicate that colchicine, an antiinflammatory agent used to treat the symptoms of gout, may increase the length of survival in patients with mild to moderate cirrhosis. Improved survival has been observed in patients with alcoholic cirrhosis. Colchicine is believed to reverse the fibrotic processes in cirrhosis, and this has improved survival (Bacon & Di Bisceglie, 2000).

**NURSING PROCESS:**

**THE PATIENT WITH HEPATIC CIRRHOSIS**

**Assessment**

Nursing assessment focuses on the onset of symptoms and the history of precipitating factors, particularly long-term alcohol abuse, as well as dietary intake and changes in the patient’s physical and mental status. The patient’s past and current patterns of alcohol use (duration and amount) are assessed and documented. It is also important to document any exposure to toxic agents encountered in the workplace or during recreational activities. The nurse documents and reports exposure to potentially hepatotoxic substances (medications, illicit IV/injection drugs, inhalants) or general anesthetic agents.

The nurse assesses the patient’s mental status through the interview and other interactions with the patient; orientation to person, place, and time is noted. The patient’s ability to carry out a job or household activities provides some information about physical and mental status. The patient’s relationships with family, friends, and coworkers may give some indication about incapacitation secondary to alcohol abuse and cirrhosis. Abdominal distention and bloating, GI bleeding, bruising, and weight changes are noted.

The nurse assesses nutritional status, which is of major importance in cirrhosis, by daily weights and monitoring of plasma proteins, transferrin, and creatinine levels.

**Diagnosis**

**NURSING DIAGNOSES**

Based on all the assessment data, the patient’s major nursing diagnoses may include the following:

- Activity intolerance related to fatigue, general debility, muscle wasting, and discomfort
- Imbalanced nutrition, less than body requirements, related to chronic gastritis, decreased GI motility, and anorexia
- Impaired skin integrity related to compromised immunologic status, edema, and poor nutrition
Risk for injury and bleeding related to altered clotting mechanisms

**COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS**

Based on assessment data, potential complications may include:

- Bleeding and hemorrhage
- Hepatic encephalopathy
- Fluid volume excess

**Planning and Goals**

The goals for the patient may include increased participation in activities, improvement of nutritional status, improvement of skin integrity, decreased potential for injury, improvement of mental status, and absence of complications.

**Nursing Interventions**

**PROMOTING REST**

The patient with active liver disease requires rest and other supportive measures to permit the liver to reestablish its functional ability. If the patient is hospitalized, weight and fluid intake and output are measured and recorded daily. The nurse adjusts the patient’s position in bed for maximal respiratory efficiency, which is especially important if ascites is marked because it interferes with adequate thoracic excursion. Oxygen therapy may be required in liver failure to oxygenate the damaged cells and prevent further cell destruction.

Rest reduces the demands on the liver and increases the liver’s blood supply. Because the patient is susceptible to the hazards of immobility, efforts to prevent respiratory, circulatory, and vascular disturbances are initiated. These measures may help prevent such problems as pneumonia, thrombophlebitis, and pressure ulcers. When nutritional status improves and strength increases, the nurse encourages the patient to increase activity gradually. Activity and mild exercise, as well as rest, are planned.

**IMPROVING NUTRITIONAL STATUS**

The patient with cirrhosis who has no ascites or edema and exhibits no signs of impending hepatic coma should receive a nutritious, high-protein diet if tolerated, supplemented by vitamins of the B complex and others as indicated (including vitamins A, C, K and folic acid). Because proper nutrition is so important, the nurse makes every effort to encourage the patient to eat. This is as important as any medication. Often small, frequent meals are tolerated better than three large meals because of the abdominal pressure exerted by ascites. Protein supplements may also be indicated.

Patient preferences are considered. Patients with prolonged or severe anorexia, or those who are vomiting or eating poorly for any reason, may receive nutrients enterally or parenterally.

Patients with fatty stools (steatorrhea) should receive water-soluble forms of fat-soluble vitamins—A, D, and E (Aquasol A, D, and E). Folic acid and iron are prescribed to prevent anemia. If the patient shows signs of impending or advancing coma, the amount of protein in the diet is decreased temporarily. In the absence of hepatic encephalopathy, a moderate-protein, high-calorie intake is provided, with protein foods of high biologic value. A diet containing 1 to 1.5 g of protein per kilogram of body weight per day is required unless the patient is malnourished. Protein is restricted if encephalopathy develops. Incorporating vegetable protein to meet protein needs may decrease the risk of encephalopathy. Sodium restriction is also indicated to prevent ascites.

A high-calorie intake should be maintained, and supplemental vitamins and minerals should be provided (eg, oral potassium if the serum potassium level is normal or low and if renal function is normal).

**PROVIDING SKIN CARE**

Providing careful skin care is important because of subcutaneous edema, the patient’s immobility, jaundice, and increased susceptibility to skin breakdown and infection. Frequent position changes are necessary to prevent pressure ulcers. It is important to avoid irritating soaps and the use of adhesive tape to prevent trauma to the skin. Lotion may be soothing to irritated skin; the nurse takes measures to minimize scratching by the patient.

**REDUCING RISK OF INJURY**

The nurse protects the patient with cirrhosis from falls and other injuries. The side rails should be in place and padded with blankets in case the patient becomes agitated or restless. To minimize agitation, the nurse orients the patient to time and place and explains all procedures. The nurse instructs the patient to ask for assistance to get out of bed. The nurse carefully evaluates any injury because of the possible risk of internal bleeding.

Because of the risk for bleeding from abnormal clotting, the patient should use an electric rather than a safety razor. A soft-bristled toothbrush will help to minimize bleeding gums, and pressure applied to all venipuncture sites will help to minimize bleeding.

**MONITORING AND MANAGING POTENTIAL COMPLICATIONS**

**Bleeding and Hemorrhage**

The patient is at increased risk for bleeding and hemorrhage because of decreased production of prothrombin and decreased ability of the diseased liver to synthesize the substances necessary for blood coagulation. Precautionary measures include protecting the patient with padded side rails, applying pressure to injection sites, and avoiding injury from sharp objects. The nurse observes for melena and assesses stools for blood (signs of possible internal bleeding). Vital signs are monitored regularly. Precautions are taken to minimize rupture of esophageal varices by avoiding further increases in portal pressure (discussed previously). Dietary modification and appropriate use of stool softeners may help prevent straining during defecation. The nurse closely monitors the patient for GI bleeding and keeps readily available equipment (Sengstaken—Blakemore tube), IV fluids, and medications needed to treat hemorrhage from esophageal and gastric varices.

If hemorrhage occurs, the nurse assists the physician in initiating measures to halt the bleeding, administering fluid and blood component therapy and medications. The patient with massive hemorrhage from bleeding esophageal or gastric varices may be transferred to the intensive care unit and may require emergency surgery or other treatment modalities. The patient and family require explanations about the event and the necessary treatment.

**Hepatic Encephalopathy**

Hepatic encephalopathy and coma, possible complications of cirrhosis, may present as deteriorating mental status and dementia as well as physical signs such as abnormal voluntary and involuntary movements. Hepatic encephalopathy is mainly caused by the ac-
cumulation of ammonia in the blood and its effect on cerebral metabolism. Many factors predispose the patient with cirrhosis to hepatic encephalopathy; therefore, the patient may require extensive diagnostic testing to identify hidden sources of bleeding and ammonia.

Treatment may include the use of lactulose and nonabsorbable intestinal tract antibiotics to decrease ammonia levels, modification in medications to eliminate those that may precipitate or worsen hepatic encephalopathy, and bed rest to minimize energy expenditure.

Monitoring is an essential nursing function to identify early deterioration in mental status. The nurse monitors the patient’s mental status closely and reports changes so that treatment of encephalopathy can be initiated promptly. Because electrolyte disturbances can contribute to encephalopathy, serum electrolyte levels are carefully monitored and corrected if abnormal. Oxygen is administered if oxygen desaturation occurs. The nurse monitors for fever or abdominal pain, which may signal the onset of bacterial peritonitis or other infection (see the discussion of hepatic encephalopathy in the “Hepatic Dysfunction” section of this Chapter).

**Fluid Volume Excess**

Patients with advanced chronic liver disease develop cardiovascular abnormalities. These occur due to an increased cardiac output and decreased peripheral vascular resistance, possibly resulting from the release of vasodilators. A hyperdynamic circulatory state develops in patients with cirrhosis, and plasma volume increases. This increase in circulating plasma volume may be due in part to splanchnic venous congestion (Bircher et al., 1999). The greater the degree of hepatic decompensation, the more severe the hyperdynamic state. Close assessment of the cardiovascular and respiratory status is key for the nurse caring for patients with this disorder. Pulmonary compromise is always a potential complication of end-stage liver disease due to plasma volume excess, making prevention of pulmonary complications an important role for the nurse. Administering diuretics, implementing fluid restrictions, and enhancing patient positioning can optimize pulmonary function. Fluid retention may be noted in the development of ascites and lower extremity swelling and dyspnea. Monitoring intake and output, daily weight changes, changes in abdominal girth, and edema formation is part of nursing assessment in the hospital or in the home setting. Patients are also monitored for nocturia and, later, oliguria as these states indicate increasing severity of liver function (Bacon & Di Bisceglie, 2000).

**PROMOTING HOME AND COMMUNITY-BASED CARE**

**Teaching Patients Self-Care**

During the patient’s hospital stay, the nurse and other health care providers prepare the patient with cirrhosis for discharge, focusing on dietary instruction. Of greatest importance is the exclusion of alcohol from the diet. The patient may need referral to Alcoholics Anonymous, psychiatric care, or counseling or may benefit from support from a spiritual advisor.

Sodium restriction will continue for a considerable time, if not permanently. The patient will require written instructions, teaching, reinforcement, and support from the staff as well as the family members.

The success of treatment depends on convincing the patient of the need to adhere completely to the therapeutic plan. This includes rest, lifestyle changes, adequate dietary intake, and the elimination of alcohol. The nurse also instructs the patient and family about the symptoms of impending encephalopathy, possible bleeding tendencies, and susceptibility to infection.

Recovery is neither rapid nor easy; there are frequent setbacks and apparent lack of improvement. Many patients find it difficult to refrain from using alcohol for comfort or escape. The nurse has a significant role in offering support and encouragement to this patient.

**Continuing Care**

Referral of the patient for home care may assist the patient in dealing with the transition from hospital to home, where the use of alcohol may have been an important part of normal home and social life. The home care nurse assesses the patient’s progress at home and the manner in which the patient and family cope with the elimination of alcohol and the dietary restrictions. The nurse also reinforces previous teaching and answers questions that may not have occurred to the patient or family until the patient is back home and trying to establish new patterns of eating, drinking, and lifestyle. For an overall view of the nursing management of the patient with impaired liver function, refer to the Plan of Nursing Care.

**Evaluation**

**EXPECTED PATIENT OUTCOMES**

Expected patient outcomes may include:

1. Participates in activities
   a.Plans activities and exercises to allow alternating periods of rest and activity
   b.Reports increased strength and well-being
   c.Participates in hygiene care

2. Increases nutritional intake
   a.Demonstrates intake of appropriate nutrients and avoidance of alcohol as reflected by diet log
   b.Gains weight without increased edema and ascites formation
   c.Reports decrease in GI disturbances and anorexia
   d.Identifies foods and fluids that are nutritious and allowed on diet or restricted from diet
   e.Adheres to vitamin therapy regimen
   f.Describes the rationale for small, frequent meals

3. Exhibits improved skin integrity
   a.Has intact skin without evidence of breakdown, infection, or trauma
   b.Demonstrates normal turgor of skin of extremities and trunk, without edema
   c.Changes position frequently and inspects bony prominences daily
   d.Uses lotions to decrease pruritus

4. Avoids injury
   a.Is free of ecchymotic areas or hematoma formation
   b.States rationale for side rails and asks for assistance to get out of bed
   c.Uses measures to prevent trauma (eg, uses electric razor and soft toothbrush, blows nose gently, arranges furniture to prevent bumps and falls, avoids straining during defecation)

5. Is free of complications
   a.Reports absence of frank bleeding from GI tract (ie, absence of melena and hematemesis)
   b.Is oriented to time, place, and person and demonstrates normal attention span
   c.Has serum ammonia level within normal limits
   d.Identifies early, reportable signs of impaired thought processes

(text continues on page 1113)
**Plan of Nursing Care**

**The Patient With Impaired Liver Function**

<table>
<thead>
<tr>
<th>Nursing Interventions</th>
<th>Rationale</th>
<th>Expected Outcomes</th>
</tr>
</thead>
</table>
| **Nursing Diagnosis**: Activity intolerance related to fatigue, lethargy, and malaise  
**Goal**: Patient reports decrease in fatigue and reports increased ability to participate in activities  
1. Assess level of activity tolerance and degree of fatigue, lethargy, and malaise when performing routine ADLs.  
2. Assist with activities and hygiene when fatigued.  
3. Encourage rest when fatigued or when abdominal pain or discomfort occurs.  
4. Assist with selection and pacing of desired activities and exercise.  
5. Provide diet high in carbohydrates with protein intake consistent with liver function.  
2. Promotes exercise and hygiene within patient’s level of tolerance  
3. Conserves energy and protects the liver  
4. Stimulates patient’s interest in selected activities  
5. Provides calories for energy and protein for healing  
6. Provides additional nutrients | • Exhibits increased interest in activities and events  
• Participates in activities and gradually increases exercise within physical limits  
• Reports increased strength and well-being  
• Reports absence of abdominal pain and discomfort  
• Plans activities to allow ample periods of rest  
• Takes vitamins as prescribed |

**Nursing Diagnosis**: Imbalanced nutrition: less than body requirements, related to abdominal distention and discomfort and anorexia  
**Goal**: Positive nitrogen balance, no further loss of muscle mass; meets nutritional requirements  
1. Assess dietary intake and nutritional status through diet history and diary, daily weight measurements and laboratory data.  
2. Provide diet high in carbohydrates with protein intake consistent with liver function.  
3. Assist patient in identifying low-sodium foods.  
4. Elevate the head of the bed during meals.  
5. Provide oral hygiene before meals and pleasant environment for meals at meal time.  
6. Offer smaller, more frequent meals (6 per day).  
7. Encourage patient to eat meals and supplementary feedings.  
8. Provide attractive meals and an aesthetically pleasing setting at meal time.  
10. Apply an ice collar for nausea.  
11. Administer medications prescribed for nausea, vomiting, diarrhea, or constipation.  
12. Encourage increased fluid intake and exercise if the patient reports constipation. | 1. Identifies deficits in nutritional intake and adequacy of nutritional state  
2. Provides calories for energy, sparing protein for healing  
3. Reduces edema and ascites formation  
4. Reduces discomfort from abdominal distention and decreases sense of fullness produced by pressure of abdominal contents and ascites on the stomach  
5. Promotes positive environment and increased appetite; reduces unpleasant taste  
6. Decreases feeling of fullness, bloating  
7. Encouragement is essential for the patient with anorexia and gastrointestinal discomfort.  
8. Promotes appetite and sense of well-being  
9. Eliminates “empty calories” and further damage from alcohol  
10. May reduce incidence of nausea  
11. Reduces gastrointestinal symptoms and discomforts that decrease the appetite and interest in food  
12. Promotes normal bowel pattern and reduces abdominal discomfort and distention | • Exhibits improved nutritional status by increased weight (without fluid retention) and improved laboratory data.  
• States rationale for dietary modifications  
• Identifies foods high in carbohydrates and within protein requirements (moderate to high protein in cirrhosis and hepatitis, low protein in hepatic failure)  
• Reports improved appetite  
• Participates in oral hygiene measures  
• Reports increased appetite; identifies rationale for smaller, frequent meals  
• Demonstrates intake of high-calorie diet; adheres to protein restriction  
• Identifies foods and fluids that are nutritious and permitted on diet  
• Gains weight without increased edema or ascites formation  
• Reports increased appetite and well-being  
• Excludes alcohol from diet  
• Takes medications for gastrointestinal disorders as prescribed  
• Reports normal gastrointestinal function with regular bowel function | (continued)
### Nursing Interventions

#### Nursing Diagnosis: Impaired skin integrity related to pruritus from jaundice and edema

**Goal:** Decrease potential for pressure ulcer development; breaks in skin integrity

<table>
<thead>
<tr>
<th>Nursing Interventions</th>
<th>Rationale</th>
<th>Expected Outcomes</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Assess degree of discomfort related to pruritus and edema.</td>
<td>1. Assists in determining appropriate interventions.</td>
<td>• Exhibits intact skin without redness, excoriation, or breakdown</td>
</tr>
<tr>
<td>2. Note and record degree of jaundice and extent of edema.</td>
<td>2. Provides baseline for detecting changes and evaluating effectiveness of interventions.</td>
<td>• Reports relief from pruritus</td>
</tr>
<tr>
<td>3. Keep patient’s fingernails short and smooth.</td>
<td>3. Prevents skin excoriation and infection from scratching.</td>
<td>• Exhibits no skin excoriation from scratching</td>
</tr>
<tr>
<td>4. Provide frequent skin care; avoid use of soaps and alcohol-based lotions.</td>
<td>4. Removes waste products on skin while preventing dryness of skin.</td>
<td>• Uses nondrying soaps and lotions. States rationale for use of nondrying soaps and lotions.</td>
</tr>
<tr>
<td>5. Massage every 2 hours with emollients; turn every 2 hours.</td>
<td>5. Promotes mobilization of edema.</td>
<td>• Turns self periodically. Exhibits reduced edema of dependent parts of the body.</td>
</tr>
<tr>
<td>6. Initiate use of alternating-pressure mattress or low air loss bed.</td>
<td>6. Minimizes prolonged pressure on bony prominences susceptible to breakdown.</td>
<td>• Exhibits no areas of skin breakdown</td>
</tr>
<tr>
<td>7. Recommend avoiding use of harsh detergents.</td>
<td>7. May decrease skin irritation and need for scratching.</td>
<td>• Exhibits decreased edema; normal skin turgor</td>
</tr>
<tr>
<td>8. Assess skin integrity every 4–8 hours. Instruct patient and family in this activity.</td>
<td>8. Edematous skin and tissue has compromised nutrient supply and is vulnerable to pressure and trauma.</td>
<td></td>
</tr>
<tr>
<td>10. Perform range of motion exercises every 4 hours; elevate edematous extremities whenever possible.</td>
<td>10. Promotes mobilization of edema.</td>
<td></td>
</tr>
</tbody>
</table>

#### Nursing Diagnosis: High risk for injury related to altered clotting mechanisms and altered level of consciousness

**Goal:** Reduced risk of injury

<table>
<thead>
<tr>
<th>Nursing Interventions</th>
<th>Rationale</th>
<th>Expected Outcomes</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Assess level of consciousness and cognitive level.</td>
<td>1. Assists in determining patient’s ability to protect self and comply with required self-protective actions; may detect deterioration of hepatic function.</td>
<td>• Is oriented to time, place, and person</td>
</tr>
<tr>
<td>2. Provide safe environment (pad side rails, remove obstacles in room, prevent falls).</td>
<td>2. Minimizes falls and injury if falls occur.</td>
<td>• Exhibits no hallucinations, and demonstrates no efforts to get up unassisted or to leave hospital</td>
</tr>
<tr>
<td>3. Provide frequent surveillance to orient patient and avoid use of restraints.</td>
<td>3. Protects patient from harm while stimulating and orienting patient; use of restraints may disturb patient further.</td>
<td>• Exhibits no ecchymoses (bruises), cuts, or hematoma</td>
</tr>
<tr>
<td>4. Replace sharp objects (razors) with safer items.</td>
<td>4. Avoids cuts and bleeding.</td>
<td>• Uses electric razor rather than sharp-edged razor</td>
</tr>
<tr>
<td>5. Observe each stool for color, consistency, and amount.</td>
<td>5. Permits detection of bleeding in gastrointestinal tract.</td>
<td>• Exhibits absence of frank bleeding from gastrointestinal tract</td>
</tr>
<tr>
<td>6. Be alert for symptoms of anxiety, epigastric fullness, weakness, and restlessness.</td>
<td>6. May indicate early signs of bleeding and shock.</td>
<td>• Exhibits absence of restlessness, epigastric fullness, and other indicators of hemorrhage and shock</td>
</tr>
<tr>
<td>7. Test each stool and emesis for occult blood.</td>
<td>7. Detects early evidence of bleeding.</td>
<td>• Exhibits negative results of test for occult gastrointestinal bleeding</td>
</tr>
<tr>
<td>8. Observe for hemorrhagic manifestations: ecchymosis, epistaxis, petechiae, and bleeding gums.</td>
<td>8. Indicates altered clotting mechanisms.</td>
<td>• Is free of ecchymotic areas or hematoma formation</td>
</tr>
<tr>
<td>9. Record vital signs at frequent intervals, depending on patient acuity (every 1–4 hours).</td>
<td>9. Provides baseline and evidence of hypovolemia, and hemorrhagic shock.</td>
<td>• Exhibits normal vital signs</td>
</tr>
<tr>
<td>10. Keep patient quiet and limit activity.</td>
<td>10. Minimizes risk of bleeding and straining.</td>
<td>• Maintains rest and remains quiet if active bleeding occurs</td>
</tr>
<tr>
<td>11. Assist physician in passage of tube for esophageal balloon tamponade, if its insertion is indicated.</td>
<td>11. Promotes nontraumatic insertion of tube in anxious and combative patient for immediate treatment of bleeding.</td>
<td>• Identifies rationale for blood transfusions and measures to treat bleeding</td>
</tr>
<tr>
<td></td>
<td></td>
<td>• Uses measures to prevent trauma (eg, uses soft toothbrush, blows nose gently, avoids bumps and falls, avoids straining during defecation).</td>
</tr>
<tr>
<td></td>
<td></td>
<td>• Experiences no side effects of medications</td>
</tr>
<tr>
<td></td>
<td></td>
<td>• Takes all medications as prescribed</td>
</tr>
</tbody>
</table>

(continued)
### Plan of Nursing Care

#### The Patient With Impaired Liver Function (Continued)

<table>
<thead>
<tr>
<th>Nursing Interventions</th>
<th>Rationale</th>
<th>Expected Outcomes</th>
</tr>
</thead>
</table>
| 12. Observe during blood transfusions. | 12. Permits detection of transfusion reactions (risk is increased with multiple blood transfusions needed for active bleeding from esophageal varices) | • Identifies rationale for precautions with use of all medications  
• Cooperates with treatment modalities |
| 13. Measure and record nature, time, and amount of vomitus. | 13. Assists in evaluating extent of bleeding and blood loss | |
| 14. Maintain patient in fasting state, if indicated. | 14. Reduces risk of aspiration of gastric contents and minimizes risk of further trauma to esophagus and stomach by preventing vomiting | |
| 15. Administer vitamin K as prescribed. | 15. Promotes clotting by providing fat-soluble vitamin necessary for clotting. | |
| 16. Remain with patient during episodes of bleeding. | 16. Reassures anxious patient and permits monitoring and detection of further needs of the patient | |
| 17. Offer cold liquids by mouth when bleeding stops (if prescribed). | 17. Minimizes risk of further bleeding by promoting vasoconstriction of esophageal and gastric blood vessels | |
| 18. Institute measures to prevent trauma:  
  a. Maintain safe environment.  
  b. Encourage gentle blowing of nose.  
  c. Prevents trauma to oral mucosa while promoting good oral hygiene  
  d. Promotes healing  
  e. Minimizes bleeding into tissues by promoting local vasoconstriction  
  f. Permits detection of new bleeding sites and monitoring of previous sites of bleeding  
  g. Minimizes oozing and blood loss from repeated injections | 18. Promotes safety of patient  
  a. Minimizes risk of trauma and bleeding by avoiding falls and cuts, etc.  
  b. Reduces risk of nosebleed (epistaxis) secondary to trauma and decreased clotting | |
| 19. Administer medications carefully; monitor for side effects. | 19. Reduces risk of side effects secondary to damaged liver’s inability to detoxify (metabolize) medications normally | |

### Nursing Diagnosis:

**Disturbed body image related to changes in appearance, sexual dysfunction, and role function**

**Goal:** Patient verbalizes feelings consistent with improvement of body image and self-esteem

- 1. Provides information for assessing impact of changes in appearance, sexual function, and role on the patient and family
- 2. Enables patient to identify and express concerns; encourages patient and significant others to share these concerns
- 3. Permits encouragement of those coping strategies that are familiar to patient and have been effective in the past
- 4. Encourages patient to continue safe roles and functions while encouraging exploration of alternatives
- • Verbalizes concerns related to changes in appearance, life, and lifestyle
- • Shares concerns with significant others
- • Identifies past coping strategies that have been effective
- • Uses past effective coping strategies to deal with changes in appearance, life, and lifestyle
- • Maintains good grooming and hygiene
- • Identifies short-term goals and strategies to achieve them
- • Exercises an active role in decision making about self and care

## The Patient With Impaired Liver Function (Continued)

### Nursing Interventions

<table>
<thead>
<tr>
<th>Interventions</th>
<th>Rationale</th>
<th>Expected Outcomes</th>
</tr>
</thead>
<tbody>
<tr>
<td>5. Assist patient in identifying short-term goals.</td>
<td>5. Accomplishing these goals serves as positive reinforcement and increases self-esteem.</td>
<td>• Identifies resources that are not harmful</td>
</tr>
<tr>
<td>6. Encourage and assist patient in decision making about care.</td>
<td>6. Promotes patient’s control of life and improves sense of well-being and self-esteem</td>
<td>• Verbalizes that some of previous lifestyle practices have been harmful</td>
</tr>
<tr>
<td>7. Identify with patient resources to provide additional support (counselor, spiritual advisor).</td>
<td>7. Assists patient in identifying resources and accepting assistance from others when indicated</td>
<td>• Uses healthy expressions of frustration, anger, anxiety</td>
</tr>
<tr>
<td>8. Assist patient in identifying previous practices that may have been harmful to self (alcohol and drug abuse).</td>
<td>8. Recognition and acknowledgment of the harmful effects of these practices are necessary for identifying a healthier lifestyle.</td>
<td></td>
</tr>
</tbody>
</table>

### Nursing Diagnosis: Chronic pain and discomfort related to enlarged tender liver and ascites

**Goal:** Increased level of comfort

<table>
<thead>
<tr>
<th>Interventions</th>
<th>Rationale</th>
<th>Expected Outcomes</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Maintain bed rest when patient experiences abdominal discomfort.</td>
<td>1. Reduces metabolic demands and protects the liver</td>
<td>• Reports pain and discomfort if present</td>
</tr>
<tr>
<td>2. Administer antispasmodic and sedative agents as prescribed.</td>
<td>2. Reduces irritability of the gastrointestinal tract and decreases abdominal pain and discomfort</td>
<td>• Maintains bed rest and decreases activity in presence of pain</td>
</tr>
<tr>
<td>3. Observe, record, and report presence and character of pain and discomfort.</td>
<td>3. Provides baseline to detect further deterioration of status and to evaluate interventions</td>
<td>• Takes antispasmodic and sedatives as indicated and as prescribed</td>
</tr>
<tr>
<td>4. Reduce sodium and fluid intake if prescribed.</td>
<td>4. Minimizes further formation of ascites</td>
<td>• Reports decreased pain and abdominal discomfort</td>
</tr>
<tr>
<td>5. Prepare patient and assist with paracentesis.</td>
<td>5. Removal of ascites fluid may decrease abdominal discomfort</td>
<td>• Exhibits decreased abdominal girth and appropriate weight changes</td>
</tr>
</tbody>
</table>

### Nursing Diagnosis: Fluid volume excess related to ascites and edema formation

**Goal:** Restoration of normal fluid volume

<table>
<thead>
<tr>
<th>Interventions</th>
<th>Rationale</th>
<th>Expected Outcomes</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Restrict sodium and fluid intake if prescribed.</td>
<td>1. Minimizes formation of ascites and edema</td>
<td>• Consumes diet low in sodium and within prescribed fluid restriction</td>
</tr>
<tr>
<td>2. Administer diuretics, potassium, and protein supplements as prescribed.</td>
<td>2. Promotes excretion of fluid through the kidneys and maintenance of normal fluid and electrolyte balance</td>
<td>• Takes diuretics, potassium, and protein supplements as indicated without experiencing side effects</td>
</tr>
<tr>
<td>3. Record intake and output every 1 to 8 hours depending on response to interventions and on patient acuity.</td>
<td>3. Indicates effectiveness of treatment and adequacy of fluid intake</td>
<td>• Exhibits increased urine output</td>
</tr>
<tr>
<td>4. Measure and record abdominal girth and weight daily.</td>
<td>4. Monitors changes in ascites formation and fluid accumulation</td>
<td>• Exhibits decreasing abdominal girth</td>
</tr>
<tr>
<td>5. Explain rationale for sodium and fluid restriction.</td>
<td>5. Promotes patient’s understanding of restriction and cooperation with it</td>
<td>• Exhibits no rapid increase in weight</td>
</tr>
<tr>
<td>6. Prepare patient and assist with paracentesis.</td>
<td>6. Paracentesis will temporarily decrease amount of ascites present.</td>
<td>• Identifies rationale for sodium and fluid restriction</td>
</tr>
<tr>
<td></td>
<td></td>
<td>• Shows a decrease in ascites with decreased weight</td>
</tr>
</tbody>
</table>

</thead>
<tbody>
<tr>
<td><strong>Nursing Diagnosis:</strong> Disturbed thought processes related to deterioration of liver function and increased serum ammonia level</td>
<td></td>
<td></td>
</tr>
<tr>
<td><strong>Goal:</strong> Improved mental status; safety maintained</td>
<td></td>
<td></td>
</tr>
<tr>
<td>1. Restrict dietary protein as prescribed.</td>
<td>1. Reduces source of ammonia (protein foods)</td>
<td>• Adheres to protein restriction</td>
</tr>
<tr>
<td>2. Give frequent, small feedings of carbohydrates.</td>
<td>2. Promotes consumption of adequate carbohydrates for energy requirements and spares protein from breakdown for energy</td>
<td>• Demonstrates an interest in events and activities in environment</td>
</tr>
<tr>
<td>3. Protect from infection.</td>
<td>3. Minimizes risk for further increase in metabolic requirements</td>
<td>• Demonstrates normal attention span</td>
</tr>
<tr>
<td>4. Keep environment warm and draft-free.</td>
<td>4. Minimizes shivering, which would increase metabolic requirements</td>
<td>• Follows and participates in conversation appropriately</td>
</tr>
<tr>
<td>5. Pad the side rails of the bed.</td>
<td>5. Provides protection for the patient should hepatic coma and seizure activity occur</td>
<td>• Is oriented to person, place, and time</td>
</tr>
<tr>
<td>6. Limit visitors.</td>
<td>6. Minimizes patient’s activity and metabolic requirements</td>
<td>• Remains in bed when indicated</td>
</tr>
<tr>
<td>7. Provide careful nursing surveillance to ensure patient’s safety.</td>
<td>7. Provides close monitoring of new symptoms and minimizes trauma to the confused patient</td>
<td>• Reports no urinary or fecal incontinence</td>
</tr>
<tr>
<td>8. Avoid opioids and barbiturates.</td>
<td>8. Prevents masking of symptoms of hepatic coma and prevents drug overdose secondary to reduced ability of the damaged liver to metabolize opioids and barbiturates</td>
<td>• Experiences no seizures</td>
</tr>
<tr>
<td>9. Awaken at intervals (every 2–4 hours) to assess cognitive status.</td>
<td>9. Provides stimulation to the patient and opportunity for observing the patient’s level of consciousness</td>
<td></td>
</tr>
</tbody>
</table>

| **Nursing Diagnosis:** Risk for imbalanced body temperature: hyperthermia related to inflammatory process of cirrhosis or hepatitis | | |
| **Goal:** Maintenance of normal body temperature, free from infection | | |
| 1. Record temperature regularly (every 4 hours). | 1. Provides baseline to detect fever and to evaluate interventions | • Exhibits normal temperature and reports absence of chills or sweating |
| 2. Encourage fluid intake. | 2. Corrects fluid loss from perspiration and fever and increases patient’s level of comfort | • Demonstrates adequate intake of fluids |
| 3. Apply cool sponges or icebag for elevated temperature. | 3. Promotes reduction of fever and increases patient’s comfort | • Exhibits no evidence of local or systemic infection |
| 4. Administer antibiotics as prescribed. | 4. Ensures appropriate serum concentration of antibiotics to treat infection | |
| 5. Avoid exposure to infections. | 5. Minimizes risk of further infection and further increases in body temperature and metabolic rate | |
| 6. Keep patient at rest while temperature is elevated. | 6. Reduces metabolic rate | |
| 7. Assess for abdominal pain, tenderness. | 7. May occur with bacterial peritonitis | |
Plan of Nursing Care

The Patient With Impaired Liver Function (Continued)

Nursing Interventions | Rationale | Expected Outcomes
--- | --- | ---

**Nursing Diagnosis:** Ineffective breathing pattern related to ascites and restriction of thoracic excursion secondary to ascites, abdominal distention, and fluid in the thoracic cavity  
**Goal:** Improved respiratory status

1. Elevate head of bed to at least 30 degrees.  
1. Reduces abdominal pressure on the diaphragm and permits fuller thoracic excursion and lung expansion
2. Conserve patient’s strength by providing rest periods and assisting with activities.
3. Change position every 2 hours.
4. Assist with paracentesis or thoracentesis.
   a. Explain procedure and its purpose to patient.
   b. Have patient void before paracentesis.
   c. Support and maintain position during procedure.
   d. Record both the amount and the character of fluid aspirated.
   e. Observe for evidence of coughing, increasing dyspnea, or pulse rate.
   1. Reduces abdominal pressure on the diaphragm and permits fuller thoracic excursion and lung expansion  
   2. Reduces metabolic and oxygen requirements  
   3. Promotes expansion and oxygenation of all areas of the lungs  
   4. Paracentesis and thoracentesis (performed to remove fluid from the abdominal and thoracic cavities, respectively) may be frightening to the patient.
   a. Helps obtain patient’s cooperation with procedures
   b. Prevents inadvertent bladder injury
   c. Prevents inadvertent organ or tissue injury
   d. Provides record of fluid removed and indication of severity of limitation of lung expansion by fluid
   e. Indicates irritation of the pleural space and evidence of pneumothorax or hemothorax.

2. Avoid activities that increase intra-abdominal pressure (straining, turning).
   a. Avoid coughing/sneezing.
   b. Assist patient to turn.
   c. Keep all needed items within easy reach.
   d. Use measures to prevent constipation such as adequate fluid intake; stool softeners.
   e. Ensure small meals.
   1. Allows early detection of signs and symptoms of bleeding and hemorrhage
   2. Minimizes increases in intra-abdominal pressure that could lead to rupture and bleeding of esophageal or gastric varices
   • Experiences improved respiratory status
   • Reports decreased shortness of breath
   • Reports increased strength and sense of well-being
   • Exhibits normal respiratory rate (12–18/min) with no adventitious sounds
   • Exhibits full thoracic excursion without shallow respirations
   • Exhibits normal arterial blood gases
   • Exhibits adequate oxygen saturation by pulse oximetry
   • Experiences absence of confusion or cyanosis

**Collaborative Problem:** Gastrointestinal bleeding and hemorrhage  
**Goal:** The patient will develop no episodes of gastrointestinal bleeding and hemorrhage

1. Assess patient for evidence of gastrointestinal bleeding or hemorrhage. If bleeding does occur:
   a. Monitor vital signs (blood pressure, pulse, respiratory rate) every 4 hours or more frequently, depending on acuity.
   b. Assess skin temperature, level of consciousness every 4 hours or more frequently, depending on acuity.
   c. Monitor gastrointestinal secretions and output (emesis, stool for occult or obvious bleeding). Test emesis for blood once per shift and with any change. Hematest each stool.
   d. Monitor hematocrit and hemoglobin for trends and changes.
2. Avoid activities that increase intra-abdominal pressure (straining, turning).
   a. Avoid coughing/sneezing.
   b. Assist patient to turn.
   c. Keep all needed items within easy reach.
   d. Use measures to prevent constipation such as adequate fluid intake; stool softeners.
   e. Ensure small meals.
1. Allows early detection of signs and symptoms of bleeding and hemorrhage
2. Minimizes increases in intra-abdominal pressure that could lead to rupture and bleeding of esophageal or gastric varices
• Experiences no episodes of bleeding and hemorrhage
• Vital signs are within acceptable range for patient
• No evidence of bleeding from gastrointestinal tract
• Hematocrit and hemoglobin levels within acceptable limits
• Turns and moves without straining and increasing intra-abdominal pressure
• No straining with bowel movements
• No further bleeding episodes if aggressive treatment of bleeding and hemorrhage was needed
• Patient and family state rationale for treatments
• Patient and family identify supports available to them
• Patient and family describe signs and symptoms of a recurrent bleeding episode and identify needed action

(continued)
**Plan of Nursing Care**

### The Patient With Impaired Liver Function (Continued)

<table>
<thead>
<tr>
<th>Nursing Interventions</th>
<th>Rationale</th>
<th>Expected Outcomes</th>
</tr>
</thead>
<tbody>
<tr>
<td>3. Have equipment (Blakemore tube, medications, intravenous fluids) available if indicated.</td>
<td>3. Equipment, medications, and supplies will be readily available if patient experiences bleeding from ruptured esophageal or gastric varices.</td>
<td></td>
</tr>
<tr>
<td>4. Assist with procedures and therapy needed to treat gastrointestinal bleeding and hemorrhage.</td>
<td>4. Gastrointestinal bleeding and hemorrhage require emergency measures (eg, insertion of Blakemore tube, administration of fluids and medications).</td>
<td></td>
</tr>
<tr>
<td>5. Monitor respiratory status every hour and minimize risk of respiratory complications if esophageal tamponade is needed.</td>
<td>5. The patient is at high risk for respiratory complications, including asphyxiation if gastric balloon of Blakemore tube ruptures or migrates upward.</td>
<td></td>
</tr>
<tr>
<td>6. Prepare patient physically and psychologically for other treatment modalities if needed.</td>
<td>6. The patient who experiences hemorrhage is very anxious and fearful; minimizing anxiety assists in control of hemorrhage.</td>
<td></td>
</tr>
<tr>
<td>7. Monitor patient for recurrence of bleeding and hemorrhage.</td>
<td>7. Risk of rebleeding is high with all treatment modalities used to halt gastrointestinal bleeding.</td>
<td></td>
</tr>
<tr>
<td>8. Keep family informed of patient’s status.</td>
<td>8. Family members are likely to be anxious about the patient’s status; providing information will reduce their anxiety level and promote more effective coping.</td>
<td></td>
</tr>
<tr>
<td>9. Once recovered from bleeding episode, provide patient and family with information regarding signs and symptoms of gastrointestinal bleeding.</td>
<td>9. Risk of rebleeding is high. Subtle signs may be more quickly identified.</td>
<td></td>
</tr>
</tbody>
</table>

**Collaborative Problem:** Hepatic encephalopathy

**Goal:** Patient will be maintained safely and without injury

| 1. Assess cognitive status every 4–8 hours: | 1. Data will provide baseline of patient’s cognitive status and enable detection of changes. |  |
| a. Assess patient’s orientation to person, place, and time. | 2. Medications are a common precipitating factor in development of hepatic encephalopathy in patients at risk. |  |
| b. Monitor patient’s level of activity, restlessness, and agitation. Assess for presence of flapping hand tremors (asterixis). | 3. Increases in serum ammonia level are associated with hepatic encephalopathy and coma. |  |
| c. Obtain and record daily sample of patient’s handwriting or ability to construct a simple figure (eg, star). | 4. Allows early initiation of treatment of hepatic encephalopathy and prevention of hepatic coma | |
| d. Assess neurologic signs (deep tendon reflexes, ability to follow instructions). | 5. Reduces breakdown and conversion of protein to ammonia |  |
| 2. Monitor medications to prevent administration of those that may precipitate hepatic encephalopathy (sedatives, hypnotics, analgesics). | 6. Reduces serum ammonia level |  |
| 3. Monitor laboratory data, especially serum ammonia level. | 7. The patient who develops hepatic coma is at risk for respiratory complications (ie, pneumonia, atelectasis, infection). |  |
| 4. Notify physician of even subtle changes in patient’s neurologic status and cognitive function. | 8. The patient in coma is at risk for skin breakdown and pressure ulcer formation. |  |
| 5. Limit sources of protein from diet if indicated. |  |  |
| 6. Administer medications prescribed to reduce serum ammonia level (eg, lactulose, antibiotics, glucose, benzodiazepine antagonist [Flumazenil] if indicated). |  |  |
| 7. Assess respiratory status and initiate measures to prevent complications. |  |  |
| 8. Protect patient’s skin and tissue from pressure and breakdown. |  |  |

- Remains awake, alert, and aware of surroundings
- Is oriented to time, place, and person
- Exhibits no restlessness or agitation
- Record of handwriting demonstrates no deterioration in cognitive function
- States rationale for treatment used to prevent or treat hepatic encephalopathy
- Demonstrates stable serum ammonia level within acceptable limits
- Consumes adequate caloric intake and adheres to protein restriction
- Takes medications as prescribed
- Breath sounds are normal without adventitious sounds
- Skin and tissue intact without evidence of pressure or breaks in integrity
Cancer of the Liver

Hepatic tumors may be malignant or benign. Benign liver tumors were uncommon until the widespread use of oral contraceptives. With the use of oral contraceptives, benign tumors of the liver occur most frequently in women in their reproductive years.

PRIMARY LIVER TUMORS

Few cancers originate in the liver. Primary liver tumors usually are associated with chronic liver disease, hepatitis B and C infections, and cirrhosis. Hepatocellular carcinoma (HCC) is by far the most common type of primary liver cancer, but it is rare in the United States (Bacon & Di Bisceglie, 2000). HCC is usually nonresectable because of rapid growth and metastasis. Other types of primary liver cancer include cholangiocellular carcinoma and combined hepatocellular and cholangiocellular carcinoma. If found early, resection may be possible, but early detection is unlikely. Cirrhosis, chronic infection with hepatitis B and C, and exposure to certain chemical toxins (eg, vinyl chloride, arsenic) have been implicated as causes of HCC. Cigarette smoking has also been identified as a risk factor, especially when combined with alcohol use. Some evidence suggests that aflatoxin, a metabolite of the fungus Aspergillus flavus, may be a risk factor for HCC. This is especially true in areas where HCC is endemic (ie, Asia and Africa). Aflatoxin and other similar toxic molds can contaminate food such as ground nuts and grains and may act as a co-carcinogen with hepatitis B. The risk of contamination is greatest when these foods are stored unrefrigerated in tropical or subtropical climates.

LIVER METASTASES

Metastases from other primary sites are found in the liver in about half of all advanced cancer cases (Bacon & Di Bisceglie, 2000). Malignant tumors are likely to reach the liver eventually, by way of the portal system or lymphatic channels, or by direct extension from an abdominal tumor. Moreover, the liver apparently is an ideal place for these malignant cells to thrive. Often the first evidence of cancer in an abdominal organ is the appearance of liver metastases; unless exploratory surgery or an autopsy is performed, the primary tumor may never be identified.

Clinical Manifestations

The early manifestations of malignancy of the liver include pain, a continuous dull ache in the right upper quadrant, epigastrium, or back. Weight loss, loss of strength, anorexia, and anemia may also occur. The liver may be enlarged and irregular on palpation. Jaundice is present only if the larger bile ducts are occluded by liver, pancreatic, or bile duct tumors. Ascites develops if such nodules obstruct the portal veins or if tumor tissue is seeded in the peritoneal cavity.

Assessment and Diagnostic Findings

The liver cancer diagnosis is based on clinical signs and symptoms, the history and physical examination, and the results of laboratory and x-ray studies. Increased serum levels of bilirubin, alkaline phosphatase, AST, GGT, and lactic dehydrogenase may occur. Leukocytosis (increased white blood cells), erythrocytosis (increased red blood cells), hypercalcemia, hypoglycemia, and hypocholesterolemia may also be seen on laboratory assessment.

The serum level of alpha-fetoprotein (AFP), which serves as a tumor marker, is elevated in 30% to 40% of patients with primary liver cancer. Levels of carcinoembryonic antigen (CEA), a marker of advanced cancer of the digestive tract, may be elevated. These two markers together are useful to distinguish between metastatic liver disease and primary liver cancer.

Many patients have metastases from the primary liver tumor to other sites by the time diagnosis is made; metastases occur primarily to the lung but may also occur to regional lymph nodes, adrenals, bone, kidneys, heart, pancreas, and stomach.

X-rays, liver scans, CT scans, ultrasound studies, MRI, arteriography, and laparoscopy may be part of the diagnostic workup and may be performed to determine the extent of the cancer. Positive emission tomograms (PET scans) are used to evaluate a wide range of metastatic tumors of the liver.

Confirmation of a tumor’s histology can be made by biopsy under imaging guidance (CT scan or ultrasound) or laparoscopically. Local or systemic dissemination of the tumor by needle biopsy or fine-needle biopsy can occur but is rare. Some clinicians believe that these procedures should not be performed if the tumor is thought to be resectable; rather, for primary HCC diagnosis should be confirmed by frozen section at the time of laparotomy.

Medical Management

Although surgical resection of the liver tumor is possible in some patients, the underlying cirrhosis, so prevalent in cancer of the liver, increases the risks associated with surgery. Radiation therapy and chemotherapy have been used in treating cancer of the liver with varying degrees of success. Although these therapies may prolong survival and improve quality of life by reducing pain and discomfort, their major effect is palliative.

RADIATION THERAPY

The use of external beam radiation for the treatment of liver tumors has been limited by the radiosensitivity of normal hepatocytes. Doses over 2,500 to 3,000 cGy may result in radiation hepatitis (O’Grady et al., 2000). More effective methods of delivering radiation to tumors of the liver include (1) intravenous or intraarterial injection of antibodies that are tagged with radioactive isotopes and specifically attack tumor-associated antigens and (2) percutaneous placement of a high-intensity source for interstitial radiation therapy (delivering radiation directly to the tumor cells).

CHEMOTHERAPY

Chemotherapy has been used to improve quality of life and prolong survival; it also may be used as adjuvant therapy after surgical resection of hepatic tumors. Systemic chemotherapy and regional infusion chemotherapy are two methods used to administer antineoplastic agents to patients with primary and metastatic hepatic tumors (O’Grady et al., 2000).

An implantable pump has been used to deliver a high concentration of chemotherapy to the liver through the hepatic artery. This method provides a reliable, controlled, and continuous infusion of medication that can be carried out in the patient’s home. Recent studies have begun to show some effective palliation and modestly improved survival rates (Bacon & Di Bisceglie, 2000).

PERCUTANEOUS BILIARY DRAINAGE

Percutaneous biliary or transhepatic drainage is used to bypass biliary ducts obstructed by liver, pancreatic, or bile duct tumors...
in patients with inoperable tumors or in those considered poor surgical risks. Under fluoroscopy, a catheter is inserted through the abdominal wall and past the obstruction into the duodenum. Such procedures are used to reestablish biliary drainage, relieve pressure and pain from the buildup of bile behind the obstruction, and decrease pruritus and jaundice. As a result, the patient is made more comfortable and quality of life and survival are improved.

For several days after its insertion, the catheter is opened to external drainage. The bile is observed closely for amount, color, and presence of blood and debris. Complications of percutaneous biliary drainage include sepsis, leakage of bile, hemorrhage, and reobstruction of the biliary system by debris in the catheter or from encroaching tumor. Therefore, the patient is observed for fever and chills, bile drainage around the catheter, changes in vital signs, and evidence of biliary obstruction, including increased pain or pressure, pruritus, and recurrence of jaundice.

**OTHER NONSURGICAL TREATMENTS**

Laser hyperthermia has been used to treat hepatic metastases. Heat has been directed to tumors through several methods to cause necrosis of the tumor cells while sparing normal tissue. In radiofrequency thermal ablation, a needle electrode is inserted into the liver tumor under imaging guidance. Radiofrequency energy passes through to the noninsulated needle tip, causing heat and tumor cell death from coagulation necrosis.

Immunotherapy is another treatment modality under investigation. In this therapy, lymphocytes with antitumor reactivity are administered to the patient with hepatic cancer. Regression of the tumor, the desired outcome, has been demonstrated in patients with metastatic cancer in whom standard treatment has failed.

Transcatheter arterial embolization interrupts the arterial blood flow to small tumors by injecting small particulate embolic or chemotherapeutic agents into the artery supplying the tumor. Ischemia and necrosis of the tumor occur as a result.

For multiple small lesions, ultrasound-guided injection of alcohol promotes dehydration of tumor cells and tumor necrosis (Habib, 2000; O’Grady et al., 2000).

**SURGICAL MANAGEMENT**

Surgical resection is the treatment of choice when HCC is confined to one lobe of the liver and the function of the remaining liver is considered adequate for postoperative recovery. In the case of metastasis, hepatic resection can be performed when the primary site can be completely excised and the metastasis is limited. Metastases to the liver, however, are rarely limited or solitary. Capitalizing on the regenerative capacity of the liver cells, some surgeons have successfully removed 90% of the liver. However, the presence of cirrhosis limits the ability of the liver to regenerate. Staging of liver tumors aids in predicting the likelihood of surgical cure. A staging system for liver tumors is summarized in Chart 39-11.

In preparation for surgery, the patient’s nutritional, fluid, and general physical status is assessed and efforts are undertaken to ensure the best physical condition possible. Support, explanation, and encouragement are provided to help the patient prepare psychologically for the surgery.

Extensive diagnostic studies may be performed. Specific studies may include liver scan, liver biopsy, cholangiography, selective hepatic angiography, percutaneous needle biopsy, peritoneoscopy, laparoscopy, ultrasound, CT scans, MRI, and blood tests, particularly determinations of serum alkaline phosphatase, AST, and GGT and its isoenzymes.

**Lobectomy.** Removal of a lobe of the liver is the most common surgical procedure for excising a liver tumor. If it is necessary to restrict blood flow from the hepatic artery and portal vein beyond 15 minutes, it is likely that hypothermia will be used. For a right-liver lobectomy or an extended right lobectomy (including the medial left lobe), a thoracoabdominal incision is used. An extensive abdominal incision is made for a left lobectomy.

**Cryosurgery.** In cryosurgery (cryoablation), tumors are destroyed by liquid nitrogen at −196°C. To destroy the diseased tissue, two or three freeze-and-thaw cycles are administered via probes during open laparotomy. This technique has been used alone or as an adjunct to hepatic resection in HCC and colorectal metastases not amenable to radical surgical excision. The efficacy of cryosurgery is still being evaluated; indications and outcomes require further investigation.

**Liver Transplantation.** Removing the liver and replacing it with a healthy donor organ is another way to treat liver cancer. Recurrence of the primary liver malignancy after transplantation, however, has been reported to occur in 70% to 85% of cases, and the survival time after recurrence is brief. Metastasis and recurrence may be enhanced by the immunosuppressive therapy needed to prevent rejection. The patient with small tumors may have a good prognosis after transplantation, but recurrence is common with tumors greater than 8 cm in diameter or those that are multifocal or have vascular invasion (Bacon & Di Bisceglie, 2000). See the discussion of liver transplantation that follows.
Nursing Management

If the patient has had surgery to treat liver cancer, potential problems related to cardiopulmonary involvement include vascular complications and respiratory and liver dysfunction. Metabolic abnormalities require careful attention. A constant infusion of 10% glucose may be required in the first 48 hours to prevent a precipitous fall in the blood glucose level resulting from decreased gluconeogenesis. Because extensive blood loss may occur as well, the patient will receive infusions of blood and IV fluids. The patient requires constant, close monitoring and care for the first 2 or 3 days, similar to postsurgical abdominal and thoracic nursing care.

The patient undergoing cryosurgery is monitored closely for hypothermia, hemorrhage, or bile leak; myoglobinuria can occur as a result of tissue necrosis and is minimized by hydration, diuresis, and at times medications (allopurinol) to bind to and aid in the excretion of toxic products.

If the patient will receive chemotherapy or radiation therapy in an effort to relieve symptoms, he or she may be discharged home while still receiving one or both of these therapies. The patient may also go home with a biliary drainage system in place. The need for teaching is great because of the need for the patient to participate in care and the family’s role in care at home.

PROMOTING HOME AND COMMUNITY-BASED CARE

Teaching Patients Self-Care. The nurse instructs the patient to recognize and report the complications and side effects of the chemotherapy that may occur and the actions and desired undesirable effects of the specific chemotherapy regimen. The nurse also emphasizes the importance of follow-up visits to assess the patient and the tumor’s response to chemotherapy and radiation therapy.

If the patient is receiving chemotherapy on an outpatient basis, the nurse explains the patient’s and family’s role in managing the chemotherapy infusion and in assessing the infusion/insertion site. The nurse encourages the patient to resume routine activities as soon as possible, while cautioning him or her to avoid activities that may damage the infusion pump or site.

The family and the patient at home with a biliary drainage system in place typically fear that the catheter will be dislodged. They need reassurance and instruction to reduce their fear that the catheter will fall out easily. The patient and family also require instruction on catheter care. They need to learn how to keep the catheter site clean and dry and how to assess the catheter and its insertion site. Irrigation of the catheter with sterile normal saline solution or water may be prescribed to keep the catheter patent and free of debris. The patient and caregivers are taught proper technique to avoid introducing bacteria into the biliary system or catheter during irrigation. They are instructed not to aspirate or draw back on the syringe during irrigation to prevent entry of irritating duodenal contents into the biliary tree or catheter. The patient and caregivers are also instructed about the signs of complications and are encouraged to notify the nurse or physician if problems or questions arise.

Continuing Care. In many cases, referral for home care enables the patient with liver cancer to be at home in a familiar environment with family and friends. Because of the poor prognosis associated with liver cancer, the home care nurse serves a vital role in assisting the patient and family to cope with the symptoms that may occur and the prognosis. The home care nurse assesses the patient’s physical and psychological status, the adequacy of pain relief, nutritional status, and the presence of symptoms indicating complications of treatment or progression of disease. During home visits, the nurse assesses the function of the chemotherapy pump, the infusion site, and the biliary drainage system, if indicated. The nurse collaborates with the other members of the health care team, the patient, and the family to ensure effective pain management and to manage other problems that may occur: weakness, pruritus, inadequate dietary intake, jaundice, and symptoms associated with metastasis to other sites. The home care nurse also assists the patient and family in making decisions about hospice care and assists with initiation of referrals. The patient is encouraged to discuss preferences for end-of-life care with family members and health care providers (see Chap. 17).

Liver Transplantation

Liver transplantation is used to treat life-threatening, end-stage liver disease for which no other form of treatment is available. The transplantation procedure involves total removal of the diseased liver and its replacement with a healthy liver in the same anatomic location (orthotopic liver transplantation [OLT]). Removal of the liver leaves a space for the new liver and permits anatomic reconstruction of the hepatic vasculature and biliary tract as close to normal as possible.

The success of liver transplantation depends on successful immunosuppression. Immunosuppressants currently in use include cyclosporine (Neoral), corticosteroids, azathioprine (Imuran), mycophenolate mofetil (CellCept), OKT3 (a monoclonal antibody), tacrolimus (FK506, Prograf), sirolimus (formerly known as rapamycin [Rapamune]), and antithymocyte globulin. Studies are underway to find the most effective combination of immunosuppressive agents and to identify new agents with fewer side effects (Hebert et al., 1999; Watson, Friend & Jamieson, 1999).

Despite the success of immunosuppression in reducing the incidence of rejection of transplanted organs, liver transplantation is not a routine procedure and may be accompanied by complications related to the lengthy surgical procedure, immunosuppressive therapy, infection, and the technical difficulties encountered in reconstructing the blood vessels and biliary tract. Long-standing systemic problems resulting from the primary liver disease may complicate the preoperative and postoperative course. Previous surgery of the abdomen, including procedures to treat complications of advanced liver disease (ie, shunt procedures used to treat portal hypertension and esophageal varices) increase the complexity of the transplantation procedure.

The indications for liver transplantation are not as limited today as they were when the procedure was first introduced, due to advances in immunosuppressive therapy, improvements in biliary tract reconstruction, and in some cases the use of venovenous bypass. General indications for liver transplantation include irreversible advanced chronic liver disease, fulminant hepatic failure, metabolic liver diseases, and some hepatic malignancies. Examples of disorders that are indications for liver transplantation include hepatocellular liver disease (eg, viral hepatitis, drug- and alcohol-induced liver disease, and Wilson’s disease) and cholestatic diseases (primary biliary cirrhosis, sclerosing cholangitis, and biliary atresia).

The patient being considered for liver transplantation frequently has many systemic problems that influence preoperative and postoperative care. Because transplantation is more
difficult when the patient has developed severe GI bleeding and hepatic coma, efforts are made to perform the procedure before this stage.

Liver transplantation is now recognized as an established therapeutic modality rather than an experimental procedure to treat these disorders. As a result, the number of centers where liver transplantation is performed is increasing. Patients requiring transplantation are often referred from distant hospitals to these sites. To prepare the patient and family for liver transplantation, nurses in all settings must understand the processes and procedures of liver transplantation.

**SURGICAL PROCEDURE**

The donor liver is freed from other structures, the bile is flushed from the gallbladder to prevent damage to the walls of the biliary tract, and the liver is perfused with a preservative and cooled. Before the donor liver is placed in the recipient, it is flushed with cold lactated Ringer’s solution to remove potassium and air bubbles.

Anastomoses (connections) of the blood vessels and bile duct are performed between the donor liver and the recipient liver. Biliary reconstruction is performed with an end-to-end anastomosis of the donor and recipient common bile ducts; a stented T-tube is inserted for external drainage of bile. If an end-to-end anastomosis is not possible because of diseased or absent bile ducts, an end-to-side anastomosis is made between the common bile duct of the graft and a loop (Roux-en-Y portion) of jejunum (Fig. 39-15A); in this case, bile drainage will be internal and a T-tube will not be inserted (Maddrey et al., 2001). Figure 39-15B and C illustrates the final appearance of the grafted liver and final closure and drain placement.

Liver transplantation is a long surgical procedure, partly because the patient with liver failure often has portal hypertension.
and subsequently many venous collateral vessels that must be ligated. Blood loss during the surgical procedure may be extensive. If the patient has adhesions from previous abdominal surgery, lysis of adhesions is often necessary. If a shunt procedure was performed previously, it must be surgically reversed to permit adequate portal venous blood supply to the new liver. During the lengthy surgery, providing regular updates to the family about the progress of the operation and the patient’s status is helpful.

**COMPLICATIONS**

The postoperative complication rate is high, primarily because of technical complications or infection. Immediate postoperative complications may include bleeding, infection, and rejection. Disruption, infection, or obstruction of the biliary anastomosis and impaired biliary drainage may occur. Vascular thrombosis and stenosis are other potential complications.

**Bleeding**

Bleeding is common in the postoperative period and may result from coagulopathy, portal hypertension, and fibrinolysis caused by ischemic injury to the donor liver. Hypotension may occur in this phase secondary to blood loss. Administration of platelets, fresh-frozen plasma, and other blood products may be necessary. Hypertension is more common, but its cause is uncertain. Blood pressure elevation that is significant or sustained is treated.

**Infection**

Infection is the leading cause of death after liver transplantation. Pulmonary and fungal infections are common; susceptibility to infection is increased by the immunosuppression needed to prevent rejection (Maddrey et al., 2001). Therefore, precautions must be taken to prevent nosocomial infections by strict asepsis when manipulating arterial lines and urine, bile, and other drainage systems; obtaining specimens; and changing dressings. Meticulous hand hygiene is crucial.

**Rejection**

Rejection is a key concern. A transplanted liver is perceived by the immune system as a foreign antigen. This triggers an immune response, leading to the activation of T lymphocytes that attack and destroy the transplanted liver. Immunosuppressive agents are used long term to prevent this response and rejection of the transplanted liver. These agents inhibit the activation of immunocompetent T lymphocytes to prevent the production of effector T cells.

Although the 1- and 5-year survival rates have increased dramatically with the use of new immunosuppressive therapies, these advances are not without major side effects. A major side effect of cyclosporine, which is widely used in transplantation, is nephrotoxicity; this problem seems to be dose-related, and renal dysfunction can be reversed if the dose of cyclosporine is appropriately decreased or if its use is not initiated immediately. Cyclosporine-related side effects have caused many centers to use tacrolimus as first-line therapy because of its efficacy and lower side effect profile.

Corticosteroids, azathioprine, mycophenolate mofetil, rapamycin, antithymocyte globulin, and OKT3 are also elements of the various regimens of immunosuppression and may be used as the initial therapy to prevent rejection, or later to treat rejection. Liver biopsy and ultrasound may be required to evaluate suspected episodes of rejection.

Retransplantation is usually attempted if the transplanted liver fails, but the success rate of retransplantation does not approach that of initial transplantation.

**Nursing Management**

The patient considering transplantation and the family have difficult decisions to make about treatment, use of financial resources, and relocation to another area to be closer to the medical center. They also must cope with the patient’s long-standing health problems and perhaps social and family problems associated with behaviors that may be responsible for the patient’s liver failure. Therefore, the time during which the patient and family are considering liver transplantation and awaiting the news that a liver is available is often stressful. The nurse must be aware of these issues and attuned to the emotional and psychological status of the patient and family. Referral of the patient and family to a psychiatric liaison nurse, psychologist, psychiatrist, or spiritual advisor may be helpful to them as they deal with the stressors associated with end-stage liver disease and liver transplantation.

**PREOPERATIVE NURSING INTERVENTIONS**

If irreversible, severe liver dysfunction has been diagnosed, the patient may be a candidate for transplantation. An extensive diagnostic evaluation will be carried out to determine whether the patient is a candidate. The nurse and other health care team members provide the patient and family with full explanations about the procedure, the chances of success, and the risks, including the side effects of long-term immunosuppression. The need for close follow-up and lifelong compliance with the therapeutic regimen, including immunosuppression, is explained to the patient and family.

Once accepted as a candidate, the patient is placed on a waiting list at the transplant center and patient information is entered into the United Network for Organ Sharing (UNOS) computer system so that candidates may be matched with appropriate organs as they become available.

Unless the patient is having a segmental liver transplantation from a living donor (Chart 39-12), a liver becomes available for transplantation only with the death of another individual, who is usually healthy except for severe brain injury and brain death. Thus, the patient and family undergo a stressful waiting period, and the nurse is often the major source of support. The patient must be accessible at all times in case an appropriate liver becomes available. During this time, liver function may deteriorate further and the patient may experience other complications from the primary liver disease. Because of the current shortage of donor organs, many patients die awaiting transplantation.

Malnutrition, massive ascites, and fluid and electrolyte disturbances are treated before surgery to increase the chance of a successful outcome. If the patient’s liver dysfunction has a very rapid onset, as in fulminant hepatic failure, there is little time or opportunity for the patient to consider and weigh options and their consequences; often this patient is in a coma, and the decision to proceed with transplantation is made by the family.

The nurse coordinator is an integral member of the transplant team and plays an important role in preparing the patient for liver transplantation. The nurse serves as a patient and family advocate and assumes the important role of link between the patient and the family.
Segmental liver transplantation in adults using part of the liver of a living donor is a relatively new technique (Bacon & Di Bisceglie, 2000) that poses ethical and medical questions.

**Issues Related to Donation**

There are two key issues in donor selection:

- The living donor of the liver segment must be a volunteer, without coercion and without financial incentives.
- The potential donor must be assessed for medical conditions that would increase his or her risk, since segmental liver transplantation poses serious risks to the donor (Maddrey et al., 2001).

Other issues concern risks, benefits, and education of the donor and recipient. An acceptable level of risk and benefits must exist for the potential recipient. In addition, a satisfactory process for educating both the donor and recipient and the family (or families in the case of unrelated parties) should be in place. Informed consent for the donor must also be ensured (Maddrey et al., 2001).

**Nurse’s Role**

During the period of evaluation and planning for the elective procedure, nurses are involved in supporting and educating both parties. Addressing the concerns each may have for the other’s welfare requires a multidisciplinary approach of all transplant team members.

**POSTOPERATIVE NURSING INTERVENTIONS**

The patient is maintained in an environment as free from bacteria, viruses, and fungi as possible, because immunosuppressive medications reduce the body’s natural defenses. In the immediate postoperative period, cardiovascular, pulmonary, renal, neurologic, and metabolic functions are monitored continuously. Mean arterial and pulmonary artery pressures are monitored continuously. Cardiac output, central venous pressure, pulmonary capillary wedge pressure, arterial and mixed venous blood gases, oxygen saturation, oxygen demand and delivery, urine output, heart rate, and blood pressure are used to evaluate the patient’s hemodynamic status and intravascular fluid volume. Liver function tests, electrolyte levels, the coagulation profile, chest x-ray, electrocardiogram, and fluid output, including urine, bile, and drainage from Jackson-Pratt tubes, are monitored closely. Because the liver is responsible for the storage of glycogen and the synthesis of protein and clotting factors, these substances need to be monitored and replaced in the immediate postoperative period.

Because of the likelihood of atelectasis and an altered ventilation–perfusion ratio as a result of the insult to the diaphragm during the surgical procedure, prolonged anesthesia, immobility, and postoperative pain, the patient will have an endotracheal tube in place and will require mechanical ventilation during the initial postoperative period. Suctioning is performed as required and sterile humidification is provided.

As the vital signs and condition stabilize, efforts are made to assist the patient to recover from the trauma of this complex surgery. After removal of the endotracheal tube, the nurse encourages the patient to use an incentive spirometer to decrease the risk for atelectasis. Once the arterial lines and the urinary catheter are removed, the patient is assisted to get out of bed, to ambulate as tolerated, and to participate in self-care to prevent the complications associated with immobility. Close monitoring for signs and symptoms of liver dysfunction and rejection will continue throughout the hospital stay. Plans will be made for close follow-up after discharge as well. Teaching, initiated during the preoperative period, continues after surgery.

**PROMOTING HOME AND COMMUNITY-BASED CARE**

**Teaching Patients Self-Care.** Teaching the patient and family about long-term measures to promote health is crucial for success of the transplant and represents an important role of the nurse. The patient and family must understand why they should adhere continuously to the therapeutic regimen, with special emphasis on the methods of administration, rationale, and side effects of the prescribed immunosuppressive agents. The nurse provides written as well as verbal instructions about how and when to take the medications. To avoid running out of medication or skipping a dose, the patient must make sure that an adequate supply of medication is available. Instructions are also provided about the signs and symptoms that indicate problems that require consultation with the transplant team. The patient with a T-tube in place must be taught how to manage the tube.

**Continuing Care.** The nurse emphasizes the importance of follow-up blood tests and visits to the transplant team. Throughout blood levels of immunosuppressive agents are obtained, along with other blood tests that assess the function of the liver and kidneys. During the first months, the patient is likely to require blood tests two or three times a week. As the patient’s condition stabilizes, blood studies and visits to the transplant team are less frequent. The importance of routine ophthalmologic examinations is emphasized because of the increased incidence of cataracts and glaucoma with the long-term corticosteroid therapy used with transplantation. Regular oral hygiene and follow-up dental care, with administration of prophylactic antibiotics before dental treatments, are recommended because of the immunosuppression.

The nurse reminds the patient that although a successful transplantation will not return him or her to normal, it does increase the chances for survival and a more normal life than before transplantation if rejection and infection can be prevented. Many patients have lived successful and productive lives after receiving a liver transplant. In fact, pregnancy can be considered 1 year after transplantation. Successful outcomes have been reported, but these pregnancies are considered high risk for mother and infant (Sherlock & Dooley, 2002).

**Liver Abscesses**

Two categories of liver abscess have been identified: amebic and pyogenic. Amebic liver abscesses are most commonly caused by *Entamoeba histolytica*. Most amebic liver abscesses occur in the developing countries of the tropics and subtropics because of poor sanitation and hygiene. Pyogenic liver abscesses are much less common but are more common in developed countries than the amebic type.

**Pathophysiology**

Whenever an infection develops anywhere along the biliary or GI tract, infecting organisms may reach the liver through the biliary system, portal venous system, or hepatic arterial or lymphatic...
system. Most bacteria are destroyed promptly, but occasionally some gain a foothold. The bacterial toxins destroy the neighboring liver cells, and the resulting necrotic tissue serves as a protective wall for the organisms.

Meanwhile, leukocytes migrate into the infected area. The result is an abscess cavity full of a liquid containing living and dead leukocytes, liquefied liver cells, and bacteria. Pyogenic abscesses of this type may be either single or multiple and small. Examples of causes of pyogenic liver abscess include cholangitis and abdominal trauma.

Clinical Manifestations
The clinical picture is one of sepsis with few or no localizing signs. Fever with chills and diaphoresis, malaise, anorexia, nausea, vomiting, and weight loss may occur. The patient may complain of dull abdominal pain and tenderness in the right upper quadrant of the abdomen. Hepatomegaly, jaundice, anemia, and pleural effusion may develop. Sepsis and shock may be severe and life-threatening. In the past, the mortality rate was 100% because of the vague clinical symptoms, inadequate diagnostic tools, and inadequate surgical drainage of the abscess. With the aid of ultrasound, CT and MRI scans, and liver scans, early diagnosis and surgical drainage of the abscess have greatly reduced the mortality rate.

Assessment and Diagnostic Findings
Blood cultures are obtained but may not identify the organism. Aspiration of the liver abscess, guided by ultrasound, CT, or MRI, may be performed to assist in diagnosis and to obtain cultures of the organism. Percutaneous drainage of pyogenic abscesses is carried out to evacuate the abscess material and promote healing. A catheter may be left in place for continuous drainage; the patient must be instructed about its management.

Medical Management
Treatment includes IV antibiotic therapy; the specific antibiotic used in treatment depends on the organism identified. Continuous supportive care is indicated because of the serious condition of the patient. Open surgical drainage may be required if antibiotic therapy and percutaneous drainage are ineffective.

Nursing Management
Although the manifestations of liver abscess vary with the type of abscess, most patients appear acutely ill. Others appear to be chronically ill and debilitated. The nursing management depends on the patient’s physical status and the medical management that is indicated. For patients who undergo evacuation and drainage of the abscess, monitoring of the drainage and skin care are imperative. Strategies must be implemented to contain the drainage and to protect the patient from other sources of infection. Vital signs are monitored to detect changes in the patient’s physical status. Deterioration in vital signs or the onset of new symptoms such as increasing pain, which may indicate rupture or extension of the abscess, is reported promptly. The nurse administers IV antibiotic therapy as prescribed. The white blood cell count and other laboratory test results are monitored closely for changes consistent with worsening infection. The nurse prepares the patient for discharge by providing instruction about symptom management, signs and symptoms that should be reported to the physician, management of drainage, and the importance of taking antibiotics as prescribed.

NURSING RESEARCH PROFILE 39-1
The Experience of Liver Failure and Liver Transplantation

Purpose
Although advances in liver transplantation have increased the survival of persons who undergo the procedure, little is known about their quality of life. This study explored individuals’ perceptions of the effect a liver transplant had on their quality of life and focused on the progression from dependence to independence physically, socially, and psychologically.

Study Sample and Design
A phenomenologic approach was used; patients were interviewed in the outpatient clinic. Interviews were audiotaped and transcribed. Cluster analysis was used to identify groups of shared issues. The sample included five patients who had undergone liver transplantation for chronic liver disease at least 1 year before the study. Participants were asked about their quality of life before and after transplantation, the meaning of a good quality of life, and the transition from being dependent before transplantation to independent.

Findings
Physical problems present before transplantation prevented the subjects from fulfilling personal goals and participating in their usual activities. Their physical problems kept them from achieving a good quality of life. Following transplant, the subjects identified their interest in social integration and their desire to be treated normally. The return to independence was identified as the key factor in their quality of life. However, their family and friends restricted their return to independence by overprotecting them. The study participants identified the importance of support from liver transplant unit staff and other patients in their transition during the first 3 months following transplantation.

Nursing Implications
It is important to recognize the issues shared by liver transplant patients and to devise strategies to assist them in achieving independence after surgery. Patient and family education regarding factors such as overprotectiveness versus using good judgment in social situations can be explored before the transplant. Educating the patient’s family and friends about the need for independence is important in helping to improve the patient’s quality of life after liver transplantation.
Critical Thinking Exercises

1. A 54-year-old man is admitted to the hospital with end-stage liver disease due to postnecrotic cirrhosis from hepatitis C, which developed following a blood transfusion 9 years ago. He is on the waiting list for a liver transplant due to incapacitating ascites and until now has been managed at home with diuretics, low sodium intake, daily weights, and fluid restriction. He also requires a weekly ultrasound-guided paracentesis. He has become unresponsive to oral diuretics, and his ascites is quickly reaccumulating after the paracentesis. His serum blood urea nitrogen (BUN) and creatinine levels are also rising. He is admitted to the hospital to receive intravenous diuretics and for closer monitoring as his renal function worsens. His worsening condition has placed him high on the waiting list for a liver transplant. As his nurse, what nursing interventions would you anticipate? What are the educational needs of the patient and his family?

2. A 59-year-old white woman received an orthotopic liver transplant 6 months ago. She did well postoperatively and was discharged on immunosuppressive therapy. She now presents with a low-grade fever (99.8°F), 5-lb weight gain, tenderness over her transplanted liver, and mild jaundice. She also reports that her urine has become dark and has decreased in amount over the past 2 weeks. Her liver function test results are abnormal. Additional laboratory test results reveal that the serum level of tacrolimus (one of her immunosuppressant medications) is subtherapeutic. Describe the relationship of each of her current symptoms to liver dysfunction. What treatment would you anticipate, and what are the nursing measures for her at this time? What explanation would you give to her for her symptoms?

3. A 20-year-old college student has been diagnosed with hepatitis B. What teaching is warranted for this patient to prevent transmission to others and to reduce the risk of complications? What symptomatic treatment would you anticipate, and what are the nursing implications associated with treatment? How would patient teaching, treatment, and nursing implications differ if the patient’s diagnosis were hepatitis A? What instructions about hepatitis B or hepatitis A would you give to the patient’s family or roommates?

4. A 66-year-old man is admitted to the hospital with a tentative diagnosis of bleeding esophageal varices. Describe the monitoring you would initiate. Describe the possible management strategies to prevent bleeding and to treat active bleeding of the esophageal varices. Identify the nursing implications for each of these strategies. How would medical management and nursing care be modified if the patient had chronic obstructive pulmonary disease in addition to esophageal varices?

Assessment and Management of Patients With Biliary Disorders

**LEARNING OBJECTIVES**

On completion of this chapter, the learner will be able to:

1. Compare approaches to management of cholelithiasis.
2. Use the nursing process as a framework for care of patients with cholelithiasis and those undergoing laparoscopic or open cholecystectomy.
3. Differentiate between acute and chronic pancreatitis.
4. Use the nursing process as a framework for care of patients with acute pancreatitis.
5. Describe the nutritional and metabolic effects of surgical treatment of tumors of the pancreas.
Disorders of the biliary tract and pancreas are common and include gallbladder stones and pancreatic dysfunction. An understanding of the structure and function of the biliary tract and pancreas is essential, along with an understanding of the close link of biliary tract disorders with liver disease. Patients with acute or chronic biliary tract or pancreatic disease require care from nurses knowledgeable about the diagnostic procedures and interventions that are used in the management of gallbladder and pancreatic disorders.

**Anatomic and Physiologic Overview**

**ANATOMY OF THE GALLBLADDER**

The gallbladder, a pear-shaped, hollow, saclike organ, 7.5 to 10 cm (3 to 4 in) long, lies in a shallow depression on the inferior surface of the liver, to which it is attached by loose connective tissue. The capacity of the gallbladder is 30 to 50 mL of bile. Its wall is composed largely of smooth muscle. The gallbladder is connected to the common bile duct by the cystic duct (Fig. 40-1).

**FUNCTION OF THE GALLBLADDER**

The gallbladder functions as a storage depot for bile. Between meals, when the sphincter of Oddi is closed, bile produced by the hepatocytes enters the gallbladder. During storage, a large portion of the water in bile is absorbed through the walls of the gallbladder, so that gallbladder bile is five to ten times more concentrated than that originally secreted by the liver. When food enters the duodenum, the gallbladder contracts and the sphincter of Oddi opens, allowing the bile to enter the intestine. This response is mediated by the hormone **cholecystokinin–pancreozymin (CCK-PZ)** from the intestinal wall. Bile is composed of water and electrolytes (sodium, potassium, calcium, chloride, and bicarbonate) and significant amounts of lecithin, fatty acids, cholesterol, bilirubin, and bile salts. The bile salts, together with cholesterol, aid in emulsification of fats in the distal ileum. They then are reabsorbed into the portal blood for return to the liver and again excreted into the bile. This pathway from hepatocytes to bile to intestine and back to the hepatocytes is called the enterohepatic circulation. Because of the enterohepatic circulation, only a small fraction of the bile salts that enter the intestine are excreted in the feces. This decreases the need for active synthesis of bile salts by the liver cells.

If the flow of bile is impeded (ie, with gallstones in the bile ducts), bilirubin, a pigment derived from the breakdown of red blood cells, does not enter the intestine. As a result, bilirubin levels in the blood increase. This results, in turn, in increased renal excretion of urobilinogen, which results from conversion of bilirubin in the small intestine, and decreased excretion in the stool. These changes produce many of the signs and symptoms seen in gallbladder disorders.

**THE PANCREAS**

The pancreas, located in the upper abdomen, has **endocrine** as well as **exocrine** functions (see Fig. 40-1). The secretion of pancreatic enzymes into the gastrointestinal tract through the pancreatic duct represents its exocrine function. The secretion of insulin, glucagon, and somatostatin directly into the bloodstream represents its endocrine function.

**Exocrine Pancreas**

The secretions of the exocrine portion of the pancreas are collected in the pancreatic duct, which joins the common bile duct and enters the duodenum at the ampulla of Vater. Surrounding the ampulla is the sphincter of Oddi, which partially controls the rate at which secretions from the pancreas and the gallbladder enter the duodenum.

The secretions of the exocrine pancreas are digestive enzymes high in protein content and an electrolyte-rich fluid. The secretions are very alkaline because of their high concentration of sodium bicarbonate and are capable of neutralizing the highly acid gastric juice that enters the duodenum. The enzyme secretions include amylase, which aids in the digestion of carbohydrates; trypsin, which aids in the digestion of proteins; and lipase, which aids in the digestion of fats. Other enzymes that promote the breakdown of more complex foodstuffs are also secreted.

**Glossary**

amylase: pancreatic enzyme; aids in the digestion of carbohydrates
cholecystitis: inflammation of the gallbladder
cholecystokinin–pancreozymin (CCK-PZ): hormone; major stimulus for digestive enzyme secretion; stimulates contraction of the gallbladder
cholecystectomy: removal of the gallbladder
cholecystojejunostomy: anastomosis of the jejunum to the gallbladder to divert bile flow
cholecystostomy: opening and drainage of the gallbladder
choledocholithiasis: stones in the common duct
choledochotomy: opening into the common duct
cholelithiasis: calculi in the gallbladder
dissolution therapy: use of medications to break up/dissolve gallstones
endocrine: secreting internally; hormonal secretion of a ductless gland
endoscopic retrograde cholangiopancreatography (ERCP): an endoscopic procedure using fiberoptic technology to visualize the biliary system
exocrine: secreting externally; hormonal secretion from excretory ducts
laparoscopic cholecystectomy: removal of gallbladder through endoscopic procedure
lipase: pancreatic enzyme; aids in the digestion of fats
lithotripsy: disintegration of gallstones by shock waves
pancreaticojejunostomy: joining of the pancreatic duct to the jejunum by side-to-side anastomosis; allows drainage of the pancreatic secretions into the jejunum
pancreatitis: inflammation of the pancreas; may be acute or chronic
secretin: hormone responsible for stimulating secretion of pancreatic juice; also used as an aid in diagnosing pancreatic exocrine disease and in obtaining desquamated pancreatic cells for cytologic examination
steatorrhea: frothy, foul-smelling stools with a high fat content; results from impaired digestion of proteins and fats due to a lack of pancreatic juice in the intestine
trypsin: pancreatic enzyme; aids in digestion of proteins
Zollinger-Ellison tumor: hypersecretion of gastric acid that produces peptic ulcers as a result of a non-beta cell tumor of the pancreatic islets
Hormones originating in the gastrointestinal tract stimulate the secretion of these exocrine pancreatic juices. **Secretin** is the major stimulus for increased bicarbonate secretion from the pancreas, and the major stimulus for digestive enzyme secretion is the hormone CCK-PZ. The vagus nerve also influences exocrine pancreatic secretion.

**Endocrine Pancreas**

The islets of Langerhans, the endocrine part of the pancreas, are collections of cells embedded in the pancreatic tissue. They are composed of alpha, beta, and delta cells. The hormone produced by the beta cells is called insulin; the alpha cells secrete glucagon and the delta cells secrete somatostatin.

**INSULIN**

A major action of insulin is to lower blood glucose by permitting entry of the glucose into the cells of the liver, muscle, and other tissues, where it is either stored as glycogen or used for energy. Insulin also promotes the storage of fat in adipose tissue and the synthesis of proteins in various body tissues. In the absence of insulin, glucose cannot enter the cells and is excreted in the urine. This condition, called diabetes mellitus, can be diagnosed by high levels of glucose in the blood. In diabetes mellitus, stored fats and protein are used for energy instead of glucose, with consequent loss of body mass. (Diabetes mellitus is discussed in detail in Chap. 41.) The level of glucose in the blood normally regulates the rate of insulin secretion from the pancreas.

**GLUCAGON**

The effect of glucagon (opposite to that of insulin) is chiefly to raise the blood glucose by converting glycogen to glucose in the liver. Glucagon is secreted by the pancreas in response to a decrease in the level of blood glucose.

**SOMATOSTATIN**

Somatostatin exerts a hypoglycemic effect by interfering with release of growth hormone from the pituitary and glucagon from the pancreas, both of which tend to raise blood glucose levels.

**Endocrine Control of Carbohydrate Metabolism**

Glucose for body energy needs is derived by metabolism of ingested carbohydrates and also from proteins by the process of gluconeogenesis. Glucose can be stored temporarily in the liver, muscles, and other tissues in the form of glycogen. The endocrine system controls the level of blood glucose by regulating the rate at which glucose is synthesized, stored, and moved to and from the bloodstream. Through the action of hormones, blood glucose is normally maintained at about 100 mg/dL (5.5 mmol/L). Insulin is the primary hormone that lowers the blood glucose level. Hormones that raise the blood glucose level are glucagon, epinephrine, adrenocorticosteroids, growth hormone, and thyroid hormone.

The endocrine and exocrine functions of the pancreas are interrelated. The major exocrine function is to facilitate digestion through secretion of enzymes into the proximal duodenum. Secretin and CCK-PZ are hormones from the gastrointestinal tract that aid in the digestion of food substances by controlling the secretions of the pancreas. Neural factors also influence pancreatic enzyme secretion. Considerable dysfunction of the pancreas must occur before enzyme secretion decreases and protein and fat digestion becomes impaired. Pancreatic enzyme secretion is normally 1,500 to 2,500 mL/day.
Gerontologic Considerations

There is little change in the size of the pancreas with age. There is, however, an increase in fibrous material and some fatty deposition in the normal pancreas in patients older than 70 years of age. Some localized arteriosclerotic changes occur with age. There is also a decreased rate of pancreatic secretion (decreased lipase, amylase, and trypsin) and bicarbonate output in older patients. Some impairment of normal fat absorption occurs with increasing age, possibly because of delayed gastric emptying and pancreatic insufficiency. Decreased calcium absorption may also occur. These changes require care in interpreting diagnostic tests in the normal elderly person and in providing dietary counseling.

Disorders of the Gallbladder

Several disorders affect the biliary system and interfere with normal drainage of bile into the duodenum. These disorders include inflammation of the biliary system and carcinoma that obstructs the biliary tree. Gallbladder disease with gallstones is the most common disorder of the biliary system. Although not all occurrences of gallbladder inflammation (cholecystitis) are related to gallstones (cholelithiasis), more than 90% of patients with acute cholecystitis have gallstones. Most of the 15 million Americans with gallstones have no pain, however, and are unaware of the presence of stones. For a guide to the terminology associated with biliary disorders and procedures, see Chart 40-1.

CHOLECYSTITIS

Acute inflammation (cholecystitis) of the gallbladder causes pain, tenderness, and rigidity of the upper right abdomen that may radiate to the midsternal area or right shoulder and is associated with nausea, vomiting, and the usual signs of an acute inflammation. An empyema of the gallbladder develops if the gallbladder becomes filled with purulent fluid.

Calculous cholecystitis is the cause of more than 90% of cases of acute cholecystitis (Ahmed, Cheung & Keefe, 2000). In calculous cholecystitis, a gallbladder stone obstructs bile outflow.

Bile remaining in the gallbladder initiates a chemical reaction; autolysis and edema occur; and the blood vessels in the gallbladder are compressed, compromising its vascular supply. Gangrene of the gallbladder with perforation may result. Bacteria play a minor role in acute cholecystitis; however, secondary infection of bile with Enterobacteriaceae, Klebsiella species, and other enteric organisms occurs in about 60% of patients (Schwartz, 1999).

Acalculous cholecystitis describes acute gallbladder inflammation in the absence of obstruction by gallstones. Acalculous cholecystitis occurs after major surgical procedures, severe trauma, or burns. Other factors associated with this type of cholecystitis include torsion, cystic duct obstruction, primary bacterial infections of the gallbladder, and multiple blood transfusions. It is speculated that acalculous cholecystitis results from alterations in fluids and electrolytes and in regional blood flow in the visceral circulation. Bile stasis (lack of gallbladder contraction) and increased viscosity of the bile are also thought to play a role. The occurrence of acalculous cholecystitis with major surgical procedures or trauma makes its diagnosis difficult.

CHOLELITHIASIS

Calculi, or gallstones, usually form in the gallbladder from the solid constituents of bile; they vary greatly in size, shape, and composition (Fig. 40-2). They are uncommon in children and young adults but become increasingly prevalent after 40 years of age. The incidence of cholelithiasis increases thereafter to such an extent that up to 50% of those over the age of 70 and over 50% of those over 80 will develop stones in the bile tract (Borzellino, deManzoni & Ricci, 1999). Chart 40-2 identifies common risk factors.

Pathophysiology

There are two major types of gallstones: those composed predominantly of pigment and those composed primarily of cholesterol. Pigment stones probably form when unconjugated pigments in the bile precipitate to form stones; these stones account for about one third of cases in the United States (Donovan, 1999). The risk of developing such stones is increased in patients with cirrhosis, hemolysis, and infections of the biliary tract. Pigment stones cannot be dissolved and must be removed surgically.

Cholesterol stones account for most of the remaining cases of gallbladder disease in the United States. Cholesterol, a normal constituent of bile, is insoluble in water. Its solubility depends on bile acids and lecithin (phospholipids) in bile. In gallstone-prone patients, there is decreased bile acid synthesis and increased cholesterol synthesis in the liver, resulting in bile supersaturated with cholesterol, which precipitates out of the bile to form stones. The cholesterol-saturated bile predisposes to the formation of gallstones and acts as an irritant, producing inflammatory changes in the gallbladder.

Four times more women than men develop cholesterol stones and gallbladder disease; the women are usually older than 40, multiparous, and obese. The incidence of stone formation rises in users of oral contraceptives, estrogens, and clofibrate; these substances are known to increase biliary cholesterol saturation. The incidence of stone formation increases with age as a result of increased hepatic secretion of cholesterol and decreased bile acid synthesis. In addition, there is an increased risk because of malabsorption of bile salts in patients with gastrointestinal disease or...
T-tube fistula or in those who have had ileal resection or bypass. The incidence also increases in people with diabetes.

**Clinical Manifestations**

Gallstones may be silent, producing no pain and only mild gastrointestinal symptoms. Such stones may be detected incidentally during surgery or evaluation for unrelated problems.

The patient with gallbladder disease from gallstones may develop two types of symptoms: those due to disease of the gallbladder itself and those due to obstruction of the bile passages by a gallstone. The symptoms may be acute or chronic. Epigastric distress, such as fullness, abdominal distention, and vague pain in the right upper quadrant of the abdomen, may occur. This distress may follow a meal rich in fried or fatty foods.

**PAIN AND BILIARY COLIC**

If a gallstone obstructs the cystic duct, the gallbladder becomes distended, inflamed, and eventually infected (acute cholecystitis). The patient develops a fever and may have a palpable abdominal mass. The patient may have biliary colic with excruciating upper right abdominal pain that radiates to the back or right shoulder, is usually associated with nausea and vomiting, and is noticeable several hours after a heavy meal. The patient moves about restlessly, unable to find a comfortable position. In some patients the pain is constant rather than colicky.

Such a bout of biliary colic is caused by contraction of the gallbladder, which cannot release bile because of obstruction by the stone. When distended, the fundus of the gallbladder comes in contact with the abdominal wall in the region of the right ninth and tenth costal cartilages. This produces marked tenderness in the right upper quadrant on deep inspiration and prevents full inspiratory excursion.

The pain of acute cholecystitis may be so severe that analgesics are required. Morphine is thought to increase spasm of the sphincter of Oddi and may be avoided in many cases in favor of meperidine (Porth, 2002). This is controversial because morphine is the preferred analgesic agent for management of acute pain, and meperidine has metabolites toxic to the CNS.

If the gallstone is dislodged and no longer obstructs the cystic duct, the gallbladder drains and the inflammatory process subsides after a relatively short time. If the gallstone continues to obstruct the duct, abscess, necrosis, and perforation with generalized peritonitis may result.

**JAUNDICE**

Jaundice occurs in a few patients with gallbladder disease and usually occurs with obstruction of the common bile duct. The bile, which is no longer carried to the duodenum, is absorbed
by the blood and gives the skin and mucous membrane a yellow color. This is frequently accompanied by marked itching of the skin.

**CHANGES IN URINE AND STOOL COLOR**
The excretion of the bile pigments by the kidneys gives the urine a very dark color. The feces, no longer colored with bile pigments, are grayish, like putty, and usually described as clay-colored.

**VITAMIN DEFICIENCY**
Obstruction of bile flow also interferes with absorption of the fat-soluble vitamins A, D, E, and K. Therefore, the patient may exhibit deficiencies (eg, bleeding caused by vitamin K deficiency, which interferes with normal blood clotting) of these vitamins if biliary obstruction has been prolonged.

**Assessment and Diagnostic Findings**

**ABDOMINAL X-RAY**
An abdominal x-ray may be obtained if gallbladder disease is suggested to exclude other causes of symptoms. However, only 15% to 20% of gallstones are calcified sufficiently to be visible on such x-ray studies.

**ULTRASONOGRAPHY**
Ultrasonography has replaced oral cholecystography as the diagnostic procedure of choice because it is rapid and accurate and can be used in patients with liver dysfunction and jaundice. It does not expose patients to ionizing radiation. The procedure is most accurate if the patient fasts overnight so that the gallbladder is distended. The use of ultrasound is based on reflected sound waves. Ultrasonography can detect calculi in the gallbladder or a dilated common bile duct. It is reported to detect gallstones with 95% accuracy.

**RADIONUCLIDE IMAGING OR CHOLESCINTIGRAPHY**
Cholescintigraphy is used successfully in the diagnosis of acute cholecystitis. In this procedure, a radioactive agent is administered intravenously. It is taken up by the hepatocytes and excreted rapidly through the biliary tract. The biliary tract is then scanned, and images of the gallbladder and biliary tract are obtained. This test is more expensive than ultrasonography, takes longer to perform, exposes the patient to radiation, and cannot detect gallstones. Its use may be limited to cases in which ultrasonography is not conclusive.

**CHOLECYSTOGRAPHY**
Although it has been replaced by ultrasonography as the test of choice, cholecystography is still used if ultrasound equipment is not available or if the ultrasound results are inconclusive. Oral cholangiography may be performed to detect gallstones and to assess the ability of the gallbladder to fill, concentrate its contents, contract, and empty. An iodide-containing contrast agent excreted by the liver and concentrated in the gallbladder is administered to the patient. The normal gallbladder fills with this radiopaque substance. If gallstones are present, they appear as shadows on the x-ray film.

Contrast agents include iopanoic acid (Telepaque), iodipamide meglumine (Cholografin), and sodium ipodate (Oragrain). These agents are administered orally 10 to 12 hours before the x-ray study. To prevent contraction and emptying of the gallbladder, the patient is permitted nothing by mouth after the contrast agent is administered.

The patient is asked about allergies to iodine or seafood. If no allergy is identified, the patient receives the oral form of the contrast agent the evening before the x-rays are obtained. An x-ray of the right upper abdomen is obtained. If the gallbladder is found to fill and empty normally and to contain no stones, gallbladder disease is ruled out. If gallbladder disease is present, the gallbladder may not be visualized because of obstruction by gallstones. A repeat of the oral cholecystogram with a second dose of the contrast agent may be necessary if the gallbladder is not visualized on the first attempt.

Cholecystography in the obviously jaundiced patient is not useful because the liver cannot excrete the radiopaque dye into the gallbladder in the presence of jaundice. Oral cholecystography is likely to continue to be used as part of the evaluation of the few patients who have been treated with gallstone dissolution therapy or lithotripsy.

**ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY**
Endoscopic retrograde cholangiopancreatography (ERCP) permits direct visualization of structures that could once be seen only during laparotomy. The examination of the hepatobiliary system is carried out via a side-viewing flexible fiberoptic endoscope inserted into the esophagus to the descending duodenum (Fig. 40-3). Multiple position changes are required during the procedure, beginning in the left semiprone position to pass the endoscope.

Fluoroscopy and multiple x-rays are used during ERCP to evaluate the presence and location of ductal stones. Careful insertion of a catheter through the endoscope into the common bile duct is the most important step in sphincterotomy (division of the muscles of the biliary sphincter) for gallstone extraction via this technique. This is described later in the chapter.

**Nursing Implications.** The procedure requires a cooperative patient to permit insertion of the endoscope without damage to the gastrointestinal tract structures, including the biliary tree. Before
the procedure, the patient is given an explanation of the procedure and his or her role in it. The patient takes nothing by mouth for several hours before the procedure. Moderate sedation is used with this procedure, so the sedated patient must be monitored closely. Most endoscopists use a combination of an opioid and a benzodiazepine. Medications such as glucagon or anticholinergics may also be necessary to eliminate duodenal peristalsis to make cannulation easier. The nurse observes closely for signs of respiratory and central nervous system depression, hypotension, oversedation, and vomiting (if glucagon is given). During ERCP, the nurse monitors intravenous fluids, administers medications, and positions the patient.

After the procedure, the nurse monitors the patient’s condition, observing vital signs and monitoring for signs of perforation or infection. The nurse also monitors the patient for side effects of any medications received during the procedure and for return of the gag and cough reflexes after the use of local anesthetics.

**PERCUTANEOUS TRANSHEPATIC CHOLANGIOGRAPHY**

Percutaneous transhepatic cholangiography involves the injection of dye directly into the biliary tract. Because of the relatively large concentration of dye that is introduced into the biliary system, all components of the system, including the hepatic ducts within the liver, the entire length of the common bile duct, the cystic duct, and the gallbladder, are outlined clearly.

This procedure can be carried out even in the presence of liver dysfunction and jaundice. It is useful for distinguishing jaundice caused by liver disease (hepatocellular jaundice) from that caused by biliary obstruction, for investigating the gastrointestinal symptoms of a patient whose gallbladder has been removed, for locating stones within the bile ducts, and for diagnosing cancer involving the biliary system.

This sterile procedure is performed under moderate sedation on a patient who has been fasting; the patient receives local anesthetic and intravenous sedation. Coagulation parameters and platelet count should be normal to minimize the risk for bleeding. Broad-spectrum antibiotics are administered during the procedure due to the high prevalence of bacterial colonization from obstructed biliary systems. After infiltration with a local anesthetic agent, a flexible needle is inserted into the liver from the right side in the midclavicular line immediately beneath the right costal margin. Successful entry of a duct is noted when bile is aspirated or upon the injection of a contrast agent. Ultrasound guidance can be used for duct puncture. Bile is aspirated and samples are sent for bacteriology and cytology. A water-soluble contrast agent is injected to fill the biliary system. The fluoroscopy table is tilted and the patient repositioned to allow x-rays to be taken in multiple projections. Delayed x-ray views can identify abnormalities of more distant ducts and determine the length of a stricture or multiple strictures. Before the needle is removed, as much dye and bile as possible are aspirated to forestall subsequent leakage into the needle tract and eventually into the peritoneal cavity, thus minimizing the risk of bile peritonitis.

Table 40-1 identifies various procedures and their diagnostic uses.

**NURSING ALERT** Although the complication rate after this procedure is low, the nurse must closely observe the patient for symptoms of bleeding, peritonitis, and septicemia. The nurse should immediately report pain and indicators of these complications. Antibiotic agents are often prescribed to minimize the risk of sepsis and septic shock.

### Medical Management

The major objectives of medical therapy are to reduce the incidence of acute episodes of gallbladder pain and cholecystitis by supportive and dietary management and, if possible, to remove the cause of cholecystitis by pharmacologic therapy, endoscopic procedures, or surgical intervention.

Although nonsurgical approaches have the advantage of eliminating risks associated with surgery, they are associated with persistent symptoms or recurrent stone formation. Most of the nonsurgical approaches, including lithotripsy and dissolution of gallstones, provide only temporary solutions to the problems associated with gallstones. They are therefore rarely used in the United States. In some instances, other treatment approaches may be indicated; these are described below.
Removal of the gallbladder (cholecystectomy) through traditional surgical approaches was considered the standard approach to management for more than 100 years. However, dramatic changes have occurred in the surgical management of gallbladder disease. There is now widespread use of laparoscopic cholecystectomy (removal of the gallbladder through a small incision through the umbilicus). As a result, surgical risks have decreased, along with the length of hospital stay and the long recovery period associated with the standard surgical cholecystectomy.

**NUTRITIONAL AND SUPPORTIVE THERAPY**

Approximately 80% of the patients with acute gallbladder inflammation achieve remission with rest, intravenous fluids, nasogastric suction, analgesia, and antibiotic agents. Unless the patient’s condition deteriorates, surgical intervention is delayed until the acute symptoms subside and a complete evaluation can be carried out.

The diet immediately after an episode is usually limited to low-fat liquids. The patient can stir powdered supplements high in protein and carbohydrate into skim milk. Cooked fruits, rice or tapioca, lean meats, mashed potatoes, non–gas-forming vegetables, bread, coffee, or tea may be added as tolerated. The patient should avoid eggs, cream, pork, fried foods, cheese and rich dressings, gas-forming vegetables, and alcohol. It is important to remind the patient that fatty foods may bring on an episode. Dietary management may be the major mode of therapy in patients who have had only dietary intolerance to fatty foods and vague gastrointestinal symptoms (Dudek, 2001).

**PHARMACOLOGIC THERAPY**

Ursodeoxycholic acid (UDCA) and chenodeoxycholic acid (chenodiol or CDCA) have been used to dissolve small, radiolucent gallstones composed primarily of cholesterol. UDCA has fewer side effects than chenodiol and can be administered in smaller doses to achieve the same effect. It acts by inhibiting the synthesis and secretion of cholesterol, thereby desaturating bile. Existing stones can be reduced in size, small ones dissolved, and new stones prevented from forming. Six to 12 months of therapy are required in many patients to dissolve stones, and monitoring of the patient is required during this time. The effective dose of medication depends on body weight. This method of treatment is generally indicated for patients who refuse surgery or for whom surgery is considered too risky.

Patients with significant, frequent symptoms, cystic duct occlusion, or pigment stones are not candidates for this therapy. Symptomatic patients with acceptable operative risk are more appropriate for laparoscopic or open cholecystectomy.

**NONSURGICAL REMOVAL OF GALLSTONES**

**Dissolving Gallstones.** Several methods have been used to dissolve gallstones by infusion of a solvent (mono-octanoin or methyl tertiary butyl ether [MTBE]) into the gallbladder. The solvent can be infused through the following routes: a tube or catheter inserted percutaneously directly into the gallbladder; a tube or drain inserted through a T-tube tract to dissolve stones not removed at the time of surgery; an ERCP endoscope; or a transnasal biliary catheter.

In the last procedure, the catheter is introduced through the mouth and inserted into the common bile duct. The upper end of the tube is then rerouted from the mouth to the nose and left in place. This enables the patient to eat and drink normally while passage of stones is monitored or chemical solvents are infused to dissolve the stones. This method of dissolution of stones is not widely used in patients with gallstone disease.

**Stone Removal by Instrumentation.** Several nonsurgical methods are used to remove stones that were not removed at the time of cholecystectomy or have become lodged in the common bile duct (Fig. 40-4A, B). A catheter and instrument with a basket attached are threaded through the T-tube tract or fistula formed at the time of T-tube insertion; the basket is used to retrieve and remove the stones lodged in the common bile duct.

A second procedure involves the use of the ERCP endoscope (see Fig. 40-4C). After the endoscope is inserted, a cutting instrument is passed through the endoscope into the ampulla of Vater of the common bile duct. It may be used to cut the submucosal fibers, or papilla, of the sphincter of Oddi, enlarging the opening, which may allow the lodged stones to pass spontaneously into the duodenum. Another instrument with a small basket or balloon at its tip may be inserted through the endoscope to retrieve the stones (see Fig. 40-4D–F). Although complications after this procedure are rare, the patient must be observed closely for bleeding, perforation, and the development of pancreatitis or sepsis.

The ERCP procedure is particularly useful in the diagnosis and treatment of patients who have symptoms after biliary tract surgery, for patients with intact gallbladders, and for patients in whom surgery is particularly hazardous.

**Extracorporeal Shock-Wave Lithotripsy.** Extracorporeal shock-wave therapy (lithotripsy or ESWL) has been used for nonsurgical fragmentation of gallstones. The word *lithotripsy* is derived from *lithos*, meaning stone, and *tripsis*, meaning rubbing or friction. This invasive procedure uses repeated shock waves directed at the gallstones in the gallbladder or common bile duct to fragment the stones. The energy is transmitted to the body through a fluid-filled bag, or it may be transmitted while the patient is immersed in a water bath. The converging shock waves are directed to the stones to be fragmented.

After the stones are gradually broken up, the stone fragments pass from the gallbladder or common bile duct spontaneously, are removed by endoscopy, or are dissolved with oral bile acid or solvents. Because the procedure requires no incision and no hospitalization, patients are usually treated as outpatients, but several sessions are generally necessary.

The advent of laparoscopic cholecystectomy has reduced the use of this method to treat gallbladder stones. It is used in some centers for a small percentage of suitable patients (those with common bile duct stones who may not be surgical candidates), sometimes in combination with dissolution therapy.

**Intracorporeal Lithotripsy.** Stones in the gallbladder or common bile duct may be fragmented by means of laser pulse technology. A laser pulse is directed under fluorescent guidance with the use of devices that can distinguish between stones and tissue. The laser pulse produces rapid expansion and disintegration of plasma on the stone surface, resulting in a mechanical shock wave. Electromagnetic lithotripsy uses a probe with two electrodes that deliver electric sparks in rapid pulses, creating expansion of the liquid environment surrounding the gallstones. This results in pressure waves that cause stones to fragment. This technique can be employed percutaneously with the use of a basket or balloon catheter system or by direct visualization through an endoscope. Repeated procedures may be necessary due to stone size, local anatomy, bleeding, or technical difficulty. A nasobiliary tube can be inserted to allow for biliary decompression and prevent stone impaction in the common bile duct. This approach allows time for improvement in the patient’s clinical condition until gallstones are cleared endoscopically, percutaneously, or surgically.
Surgical treatment of gallbladder disease and gallstones is carried out to relieve persistent symptoms, to remove the cause of biliary colic, and to treat acute cholecystitis. Surgery may be delayed until the patient's symptoms have subsided or may be performed as an emergency procedure if the patient's condition necessitates it.

Preoperative Measures. A chest x-ray, electrocardiogram, and liver function tests may be performed in addition to x-ray studies of the gallbladder. Vitamin K may be administered if the prothrombin level is low. Blood component therapy may be administered before surgery. Nutritional requirements are considered; if the nutritional status is suboptimal, it may be necessary to provide intravenous glucose with protein hydrolysate supplements to aid wound healing and help prevent liver damage.

Preparation for gallbladder surgery is similar to that for any upper abdominal laparotomy or laparoscopy. Instructions and explanations are given before surgery with regard to turning and deep breathing. Pneumonia and atelectasis are possible postoperative complications that can be avoided by deep-breathing exercises and frequent turning. The patient should be informed that drainage tubes and a nasogastric tube and suction may be required during the immediate postoperative period if an open cholecystectomy is performed.

Laparoscopic Cholecystectomy. Laparoscopic cholecystectomy (Fig. 40-5) has dramatically changed the approach to the management of cholecystitis. It has become the new standard for therapy of symptomatic gallstones. Approximately 700,000 patients in the United States require surgery each year for removal of the gallbladder, and 80% to 90% of them are candidates for laparoscopic cholecystectomy (Bornman & Beckingham, 2001). If the common bile duct is thought to be obstructed by a gallstone, an ERCP with sphincterotomy may be performed to explore the duct before laparoscopy.

Before the procedure, the patient is informed that an open abdominal procedure may be necessary, and general anesthesia is administered. Laparoscopic cholecystectomy is performed through a small incision or puncture made through the abdominal wall in the umbilicus. The abdominal cavity is insufflated with carbon dioxide (pneumoperitoneum) to assist in inserting the laparoscope and to aid the surgeon in visualizing the abdominal structures. The fiberoptic scope is inserted through the small umbilical incision. Several additional punctures or small incisions are made in the abdominal wall to introduce other surgical instruments into the operative field. The surgeon visualizes the biliary system through the laparoscope; a camera attached to the scope permits a view of the intra-abdominal field to be transmitted to a television monitor. After the cystic duct is dissected, the common bile duct is imaged by ultrasound or cholangiography to evaluate the anatomy and identify stones. The cystic artery is dissected free and clipped. The gallbladder is separated away from the hepatic bed and dissected. The gallbladder is then removed from the abdominal cavity after bile and small stones are aspirated. Stone forceps also can be used to remove or crush larger stones.

The advantage of the laparoscopic procedure is that the patient does not experience the paralytic ileus that occurs with open abdominal surgery and has less postoperative abdominal pain. The patient is often discharged from the hospital on the day of surgery or within a day or two and can resume full activity and employment within a week of the surgery.

Conversion to a traditional abdominal surgical procedure may be necessary if problems are encountered during the laparoscopic procedure; this occurs in 2% to 8% of reported surgical cases.
Conversion is required more often, approximately 20% of the time, in those with acute cholecystitis (Lai et al., 1998). Careful screening of patients and identification of those at low risk for complications limits the frequency of conversion to an open abdominal procedure. With wider use of laparoscopic procedures, however, there may be an increase in the number of such conversions. The most serious complication after laparoscopic cholecystectomy is a bile duct injury.

Because of the short hospital stay, it is important to provide written as well as verbal instructions about managing postoperative pain and reporting signs and symptoms of intra-abdominal complications, including loss of appetite, vomiting, pain, distention of the abdomen, and temperature elevation. Although recovery from laparoscopic cholecystectomy is rapid, patients are drowsy afterward. The nurse must ensure that the patient has assistance at home during the first 24 to 48 hours. If pain occurs in the right shoulder or scapular area (from migration of the CO2 used to insufflate the abdominal cavity during the procedure), the nurse may recommend use of a heating pad for 15 to 20 minutes hourly, walking, and sitting up when in bed.

**Cholecystectomy.** In this procedure, the gallbladder is removed through an abdominal incision (usually right subcostal) after the cystic duct and artery are ligated. The procedure is performed for acute and chronic cholecystitis. In some patients a drain may be placed close to the gallbladder bed and brought out through a puncture wound if there is a bile leak. The drain type is chosen based on the physician’s preference. A small leak should close spontaneously in a few days with the drain preventing accumulation of bile. Usually only a small amount of serosanguinous fluid will drain in the initial 24 hours after surgery, and then the drain will be removed. The drain is usually maintained if there is excess oozing or bile leakage. Use of a T-tube inserted into the common bile duct during the open procedure is now uncommon; it is used only in the setting of a complication (i.e., retained common bile duct stone). Bile duct injury is a serious complication of this procedure but occurs less frequently than with the laparoscopic approach. Once one of the most common surgical procedures in the United States, this procedure has largely been replaced by laparoscopic cholecystectomy.

**Mini-cholecystectomy.** Mini-cholecystectomy is a surgical procedure in which the gallbladder is removed through a small incision. If needed, the surgical incision is extended to remove large gallbladder stones. Drains may or may not be used. The cost savings resulting from the shorter hospital stay have been identified as a major reason for pursuing this type of procedure. Debate exists about this procedure because it limits exposure to all the involved biliary structures.

**Choledochostomy.** Choledochostomy involves an incision into the common duct, usually for removal of stones. After the stones have been evacuated, a tube usually is inserted into the duct for drainage of bile until edema subsides. This tube is connected to gravity drainage tubing. The gallbladder also contains stones, and as a rule a cholecystectomy is performed at the same time.

**Surgical Cholecystostomy.** Cholecystostomy is performed when the patient’s condition prevents more extensive surgery or when an acute inflammatory reaction is severe. The gallbladder is surgically opened, the stones and the bile or the purulent drainage are removed, and a drainage tube is secured with a purse-string suture. The drainage tube is connected to a drainage system to
prevent bile from leaking around the tube or escaping into the peritoneal cavity. After recovery from the acute episode, the patient may return for cholecystectomy. Despite its lower risk, surgical cholecystostomy has a high mortality rate (reported as high as 20% to 30%) because of the underlying disease process.

**Percutaneous Cholecystostomy.** Percutaneous cholecystostomy has been used in the treatment and diagnosis of acute cholecystitis in patients who are poor risks for any surgical procedure or for general anesthesia. These may include patients with sepsis or severe cardiac, renal, pulmonary, or liver failure. Under local anesthesia, a fine needle is inserted through the abdominal wall and liver edge into the gallbladder under the guidance of ultrasound or computed tomography. Bile is aspirated to ensure adequate placement of the needle, and a catheter is inserted into the gallbladder to decompress the biliary tract. Almost immediate relief of pain and resolution of signs and symptoms of sepsis and cholecystitis have been reported with this procedure. Antibiotic agents are administered before, during, and after the procedure.

**Gerontologic Considerations**

Surgical intervention for disease of the biliary tract is the most common operative procedure performed in the elderly. Cholesterol saturation of bile increases with age due to increased hepatic secretion of cholesterol and decreased bile acid synthesis.

Although the incidence of gallstones increases with age, the elderly patient may not exhibit the typical picture of fever, pain, chills, and jaundice. Symptoms of biliary tract disease in the elderly may be accompanied or preceded by those of septic shock, which include oliguria, hypotension, changes in mental status, tachycardia, and tachypnea.

Although surgery in the elderly presents a risk because of preexisting associated diseases, the mortality rate from serious complications from biliary tract disease itself is also high. The risk of death and complications is increased in the elderly patient who undergoes emergency surgery for life-threatening disease of the biliary tract. Despite chronic illness in many elderly patients, elective cholecystectomy is usually well tolerated and can be carried out with low risk if expert assessment and care are provided before, during, and after the surgical procedure.

Because of recent changes in the health care system, there has been a decrease in the number of elective surgical procedures performed, including cholecystectomies. As a result, patients requiring the procedure are seen in the later stages of disease. Simultaneously, patients undergoing surgery are increasingly older than 60 years of age and have complicated acute cholecystitis. The higher risk of complications and shorter hospital stays make it essential that older patients and their family members receive specific information about signs and symptoms of complications and measures to prevent them.

**NURSING PROCESS: THE PATIENT UNDERGOING SURGERY FOR GALLBLADDER DISEASE**

**Assessment**

The patient who is to undergo surgical treatment of gallbladder disease is often admitted to the hospital or same-day surgery unit on the morning of surgery. Preadmission testing is often completed a week or more before admission; at that time, the nurse instructs the patient about the need to avoid smoking to enhance pulmonary recovery postoperatively and to avoid respiratory complications. It also is important to instruct the patient to avoid the use of aspirin and other agents (over-the-counter medications and herbal remedies) that can alter coagulation and other biochemical processes.

Assessment should focus on the patient’s respiratory status. If a traditional surgical approach is planned, the high abdominal incision required during surgery may interfere with full respiratory excursion. The nurse notes a history of smoking, previous respiratory problems, shallow respirations, a persistent or ineffective cough, and the presence of adventitious breath sounds. Nutritional status is evaluated through a dietary history and general examination performed at the time of preadmission testing. The nurse also reviews previously obtained laboratory results to obtain information about the patient’s nutritional status.

**Diagnosis**

**NURSING DIAGNOSES**

Based on all the assessment data, the major postoperative nursing diagnoses for the patient undergoing surgery for gallbladder disease may include the following:

- Acute pain and discomfort related to surgical incision
- Impaired gas exchange related to the high abdominal surgical incision (if traditional surgical cholecystectomy is performed)
- Impaired skin integrity related to altered biliary drainage after surgical intervention (if a T-tube is inserted because of retained stones in the common bile duct or another drainage device is employed)
- Imbalanced nutrition, less than body requirements, related to inadequate bile secretion
- Deficient knowledge about self-care activities related to incision care, dietary modifications (if needed), medications, reportable signs or symptoms (eg, fever, bleeding, vomiting)

**COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS**

Based on assessment data, potential complications may include:

- Bleeding
- Gastrointestinal symptoms (may be related to biliary leak)

**Planning and Goals**

The goals for the patient include relief of pain, adequate ventilation, intact skin and improved biliary drainage, optimal nutritional intake, absence of complications, and understanding of self-care routines.

**Postoperative Nursing Interventions**

After recovery from anesthesia, the nurse places the patient in the low Fowler’s position. Intravenous fluids may be given, and nasogastric suction (a nasogastric tube was probably inserted immediately before surgery for a nonlaparoscopic procedure) may be instituted to relieve abdominal distention. Water and other fluids are given in about 24 hours, and a soft diet is started when bowel sounds return.

**RELIEVING PAIN**

The location of the subcostal incision in nonlaparoscopic gallbladder surgery is likely to cause the patient to avoid turning and moving, to splint the affected site, and to take shallow breaths to prevent pain. Because full aeration of the lungs and gradually increased activity are necessary to prevent postoperative complica-
tions, the nurse should administer analgesic agents as prescribed to relieve the pain and to promote well-being in addition to helping the patient turn, cough, breathe deeply, and ambulate as indicated. Use of a pillow or binder over the incision may reduce pain during these maneuvers.

**IMPROVING RESPIRATORY STATUS**

Patients undergoing biliary tract surgery are especially prone to pulmonary complications, as are all patients with upper abdominal incisions. Thus, the nurse reminds patients to take deep breaths and cough every hour to expand the lungs fully and prevent atelectasis. The early and consistent use of incentive spirometry also helps improve respiratory function. Early ambulation prevents pulmonary complications as well as other complications, such as thrombophlebitis. Pulmonary complications are more likely to occur in the elderly and in obese patients.

**PROMOTING SKIN CARE AND BILIARY DRAINAGE**

In patients who have undergone a cholecystostomy or choledochostomy, the drainage tubes must be connected immediately to a drainage receptacle. The nurse should fasten tubing to the dressings or to the patient’s gown, with enough leeway for the patient to move without dislodging or kinking it. Because a drainage system remains attached when the patient is ambulating, the drainage bag may be placed in a bathrobe pocket or fastened so that it is below the waist or common duct level. If a Penrose drain is used, the nurse changes the dressings as required.

After these surgical procedures, the patient is observed for indications of infection, leakage of bile into the peritoneal cavity, and obstruction of bile drainage. If bile is not draining properly, an obstruction is probably causing bile to be forced back into the liver and bloodstream. Because jaundice may result, the nurse should be particularly observant of the color of the sclerae. The nurse should also note and report right upper quadrant abdominal pain, nausea and vomiting, bile drainage around any drainage tube, clay-colored stools, and a change in vital signs.

Bile may continue to drain from the drainage tract in considerable quantities for a time, necessitating frequent changes of the outer dressings and protection of the skin from irritation because bile is corrosive to the skin.

To prevent total loss of bile, the physician may want the drainage tube or collection receptacle elevated above the level of the abdomen so that the bile drains externally only if pressure develops in the duct system. Every 24 hours, the nurse measures the bile collected and records the amount, color, and character of the drainage. After several days of drainage, the tube may be clamped for an hour before and after each meal to deliver bile to the duodenum to aid in digestion. Within 7 to 14 days, the drainage tube is removed. The patient who goes home with a drainage tube in place requires instruction and reassurance about its function and care of the tube.

In all patients with biliary drainage, the nurse observes the stools daily and notes their color. Specimens of both urine and stool may be sent to the laboratory for examination for bile pigments. In this way, it is possible to determine whether the bile pigment is disappearing from the blood and is draining again into the duodenum. Maintaining a careful record of fluid intake and output is important.

**IMPROVING NUTRITIONAL STATUS**

The nurse encourages the patient to eat a diet low in fats and high in carbohydrates and proteins immediately after surgery. At the time of hospital discharge, there are usually no special dietary instructions other than to maintain a nutritious diet and avoid excessive fats. Fat restriction usually is lifted in 4 to 6 weeks when the biliary ducts dilate to accommodate the volume of bile once held by the gallbladder and when the ampulla of Vater again functions effectively. After this, when the patient eats fat, adequate bile will be released into the digestive tract to emulsify the fats and allow their digestion. This is in contrast to before surgery, when fats may not be digested completely or adequately, and flatulence may occur. However, one purpose of gallbladder surgery is to allow a normal diet.

**MONITORING AND MANAGING POTENTIAL COMPLICATIONS**

Bleeding may occur as a result of inadvertent puncture or nicking of a major blood vessel. Postoperatively, the nurse closely monitors vital signs and inspects the surgical incisions and drains, if in place, for evidence of bleeding. The nurse also periodically assesses the patient for increased tenderness and rigidity of the abdomen. If these signs and symptoms occur, they are reported to the surgeon. The nurse instructs the patient and family to report to the surgeon any change in the color of stools because this may indicate complications. Gastrointestinal symptoms, although not common, may occur with manipulation of the intestines during surgery.

After laparoscopic cholecystectomy, the nurse assesses the patient for loss of appetite, vomiting, pain, distention of the abdomen, and temperature elevation. These may indicate infection or disruption of the gastrointestinal tract and should be reported to the surgeon promptly. Because the patient is discharged soon after laparoscopic surgery, the patient and family are instructed verbally and in writing about the importance of reporting these symptoms promptly.

**PROMOTING HOME AND COMMUNITY-BASED CARE**

**Teaching Patients Self-Care**

The nurse instructs the patient about the medications that are prescribed (vitamins, anticholinergics, and antispasmodics) and their actions. It also is important to inform the patient and family about symptoms that should be reported to the physician, including jaundice, dark urine, pale-colored stools, pruritus, or signs of inflammation and infection, such as pain or fever.

Some patients report one to three bowel movements a day. This is the result of a continual trickle of bile through the choledochoduodenal junction after cholecystectomy. Usually, such frequency diminishes over a period of a few weeks to several months.

If a patient is discharged from the hospital with a drainage tube still in place, the patient and family may need instructions about its management. The nurse instructs them in proper care of the drainage tube and the importance of reporting to the physician promptly any changes in the amount or characteristics of drainage. Assistance in securing the appropriate dressings will reduce the patient’s anxiety about going home with the drain or tube still in place. (See Chart 40-3 for more details.)

**Continuing Care**

With sufficient support at home, most patients recover quickly from cholecystectomy. However, elderly or frail patients and those who live alone may require a referral for home care. During home visits, the nurse assesses the patient’s physical status, especially wound healing, and progress toward recovery. Assessing the patient for adequacy of pain relief and pulmonary exercises also is important. If the patient has a drainage system in place, the nurse assesses it for patency and appropriate management by the patient and family. Assessing for signs of infection and teaching the patient about
the signs and symptoms of infection are also important nursing interventions. The patient’s understanding of the therapeutic regimen (medications, gradual return to normal activities) is assessed, and previous teaching is reinforced. The nurse emphasizes the importance of keeping follow-up appointments and reminds the patient and family of the importance of participating in health promotion activities and recommended health screening.

**Evaluation**

**EXPECTED PATIENT OUTCOMES**

Expected patient outcomes may include:

1. Reports decrease in pain
   a. Splints abdominal incision to decrease pain
   b. Avoids foods that cause pain
   c. Uses postoperative analgesia as prescribed
2. Demonstrates appropriate respiratory function
   a. Achieves full respiratory excursion, with deep inspiration and expiration
   b. Coughs effectively, using pillow to splint abdominal incision
   c. Uses postoperative analgesia as prescribed
   d. Exercises as prescribed (e.g., turns, ambulates)
3. Exhibits normal skin integrity around biliary drainage site (if applicable)
   a. Is free of fever, abdominal pain, change in vital signs, or bile, foul-smelling drainage, or pus around drainage tube
   b. Demonstrates proper management of drainage tube (if applicable)
   c. Identifies signs and symptoms of biliary obstruction to be noted and reported
   d. Has serum bilirubin level within normal range
4. Obtains relief of dietary intolerance
   a. Maintains adequate dietary intake and avoids foods that cause gastrointestinal symptoms
   b. Reports decreased or absent nausea, vomiting, diarrhea, flatulence, and abdominal discomfort
5. Absence of complications
   a. Has normal vital signs (blood pressure, pulse, respiratory rate and pattern, and temperature)

**Chart 40-3 • PATIENT EDUCATION**

**Managing Self-Care After Laparoscopic Cholecystectomy**

**Resuming Activity**
- Begin light exercise (walking) immediately.
- Take a shower or bath after 1 or 2 days.
- Drive a car after 3 or 4 days.
- Avoid lifting objects exceeding 5 pounds after surgery, usually for 1 week.
- Resume sexual activity when desired.

**Caring for the Wound**
- Check puncture site daily for signs of infection.
- Wash puncture site with mild soap and water.
- Allow special adhesive strips on the puncture site to fall off. Do not pull them off.

**Resuming Eating**
- Resume your normal diet.
- If you had fat intolerance before surgery, gradually add fat back into your diet in small increments.

**Managing Pain**
- You may experience pain or discomfort in your right shoulder from the gas used to inflate your abdominal area during surgery. Sitting upright in bed or a chair or walking may ease the discomfort.

**Managing Follow-Up Care**
- Make an appointment with your surgeon for 7 to 10 days after discharge.
- Call your surgeon if you experience any signs or symptoms of infection at or around the puncture site: redness, tenderness, swelling, heat, or drainage.
- Call your surgeon if you experience a fever of 37.7°C (100°F) or more for 2 consecutive days.
- Call your surgeon if you develop nausea, vomiting, or abdominal pain.

**Disorders of the Pancreas**

**Pancreatitis** (inflammation of the pancreas) is a serious disorder. The most basic classification system used to describe or categorize the various stages and forms of pancreatitis divides the disorder into acute or chronic forms. Acute pancreatitis can be a medical emergency associated with a high risk for life-threatening complications and mortality, whereas chronic pancreatitis often goes undetected until 80% to 90% of the exocrine and endocrine tissue is destroyed. Acute pancreatitis does not usually lead to chronic pancreatitis unless complications develop. However, chronic pancreatitis can be characterized by acute episodes. Typically, patients are men 40 to 45 years of age with a history of alcoholism or women 50 to 55 years of age with a history of biliary disease (Hale et al., 2000).

Although the mechanisms causing pancreatic inflammation are unknown, pancreatitis is commonly described as autodigestion of the pancreas. Generally, it is believed that the pancreatic duct becomes obstructed, accompanied by hypersecretion of the exocrine enzymes of the pancreas. These enzymes enter the bile duct, where they are activated and, together with bile, back up (reflux) into the pancreatic duct, causing pancreatitis.

**ACUTE PANCREATITIS**

Acute pancreatitis ranges from a mild, self-limiting disorder to a severe, rapidly fatal disease that does not respond to any treatment. Mild acute pancreatitis is characterized by edema and inflammation confined to the pancreas. Minimal organ dysfunction is present, and return to normal usually occurs within 6 months. Although this is considered the milder form of pancreatitis, the
patient is acutely ill and at risk for hypovolemic shock, fluid and electrolyte disturbances, and sepsis. A more widespread and complete enzymatic digestion of the gland characterizes severe acute pancreatitis. The tissue becomes necrotic, and the damage extends into the retroperitoneal tissues. Local complications consist of pancreatic cysts or abscesses and acute fluid collections in or near the pancreas. Systemic complications, such as acute respiratory distress syndrome, shock, disseminated intravascular coagulopathy, and pleural effusion, can increase the mortality rate to 50% or higher (Aronson, 1999).

Gerontologic Considerations
Acute pancreatitis affects people of all ages, but the mortality rate associated with acute pancreatitis increases with advancing age. In addition, the pattern of complications changes with age. Younger patients tend to develop local complications; the incidence of multiple organ failure increases with age, possibly as a result of progressive decreases in physiologic function of major organs with increasing age. Close monitoring of major organ function (ie, lungs, kidneys) is essential, and aggressive treatment is necessary to reduce mortality from acute pancreatitis in the elderly.

Pathophysiology
Self-digestion of the pancreas by its own proteolytic enzymes, principally trypsin, causes acute pancreatitis. Eighty percent of patients with acute pancreatitis have biliary tract disease; however, only 5% of patients with gallstones develop pancreatitis. Gallstones enter the common bile duct and lodge at the ampulla of Vater, obstructing the flow of pancreatic juice or causing a reflux of bile from the common bile duct into the pancreatic duct, thus activating the powerful enzymes within the pancreas. Normally, these remain in an inactive form until the pancreatic secretions reach the lumen of the duodenum. Activation of the enzymes can lead to vasodilation, increased vascular permeability, necrosis, erosion, and hemorrhage (Quillen, 2001).

Long-term use of alcohol is commonly associated with acute episodes of pancreatitis, but the patient usually has had undiagnosed chronic pancreatitis before the first episode of acute pancreatitis occurs. Other less common causes of pancreatitis include bacterial or viral infection, with pancreatitis a complication of mumps virus. Spasm and edema of the ampulla of Vater, resulting from duodenitis, can probably produce pancreatitis. Blunt abdominal trauma, peptic ulcer disease, ischemic vascular disease, hyperlipidemia, hypercalcemia, and the use of corticosteroids, thiazide diuretics, and oral contraceptives also have been associated with an increased incidence of pancreatitis. Acute pancreatitis may follow surgery on or near the pancreas or after instrumentation of the pancreatic duct. Acute idiopathic pancreatitis accounts for up to 20% of the cases of acute pancreatitis (Hale, Moseley & Warner, 2000). In addition, there is a small incidence of hereditary pancreatitis.

The mortality rate of patients with acute pancreatitis is high (10%) because of shock, anoxia, hypotension, or fluid and electrolyte imbalances. Attacks of acute pancreatitis may result in complete recovery, may recur without permanent damage, or may progress to chronic pancreatitis. The patient admitted to the hospital with a diagnosis of pancreatitis is acutely ill and needs expert nursing and medical care.

Severity and mortality predictions of acute alcoholic pancreatitis are generally assessed using Ranson’s criteria (Tierney, McPhee & Papadakis, 2001). The Acute Physiology and Chronic Health Evaluation (APACHE) grading system may also be used. Predictors of the severity of pancreatitis and its prognosis are listed in Chart 40-4.

Clinical Manifestations
Severe abdominal pain is the major symptom of pancreatitis that causes the patient to seek medical care. Abdominal pain and tenderness and back pain result from irritation and edema of the inflamed pancreas that stimulate the nerve endings. Increased tension on the pancreatic capsule and obstruction of the pancreatic ducts also contribute to the pain. Typically, the pain occurs in the midepigastrium. Pain is frequently acute in onset, occurring 24 to 48 hours after a very heavy meal or alcohol ingestion, and it may be diffuse and difficult to localize. It is generally more severe after meals and is unrelieved by antacids. Pain may be accompanied by abdominal distention; a poorly defined, palpable abdominal mass; and decreased peristalsis. Pain caused by pancreatitis is accompanied frequently by vomiting that does not relieve the pain or nausea.

The patient appears acutely ill. Abdominal guarding is present. A rigid or board-like abdomen may develop and is generally an ominous sign; the abdomen may remain soft in the absence of peritonitis. Ecchymosis (bruising) in the flank or around the umbilicus may indicate severe pancreatitis. Nausea and vomiting are common in acute pancreatitis. The emesis is usually gastric in origin but may also be bile-stained. Fever, jaundice, mental confusion, and agitation also may occur.

Hypotension is typical and reflects hypovolemia and shock caused by the loss of large amounts of protein-rich fluid into the tissues and peritoneal cavity. The patient may develop tachycardia, cyanosis, and cold, clammy skin in addition to hypotension. Acute renal failure is common.

Respiratory distress and hypoxia are common, and the patient may develop diffuse pulmonary infiltrates, dyspnea, tachypnea, and abnormal blood gas values. Myocardial depression, hyperglycemia, hyperglycemia, and disseminated intravascular coagulopathy (DIC) may also occur with acute pancreatitis.
Assessment and Diagnostic Findings

The diagnosis of acute pancreatitis is based on a history of abdominal pain, the presence of known risk factors, physical examination findings, and diagnostic findings. Serum amylase and lipase levels are used in making the diagnosis of acute pancreatitis. In 90% of the cases, serum amylase and lipase levels usually rise in excess of three times their normal upper limit within 24 hours (Tierney, McPhee & Papadakis, 2001). Serum amylase usually returns to normal within 48 to 72 hours. Serum lipase levels may remain elevated for 7 to 14 days (Braunwald et al., 2001). Urinary amylase levels also become elevated and remain elevated longer than serum amylase levels. The white blood cell count is usually elevated; hypocalcemia is present in many patients and correlates well with the severity of pancreatitis. Transient hyperglycemia and glucosuria and elevated serum bilirubin levels occur in some patients with acute pancreatitis.

X-ray studies of the abdomen and chest may be obtained to differentiate pancreatitis from other disorders that may cause similar symptoms and to detect pleural effusions. Ultrasound and contrast-enhanced computed tomography scans are used to identify an increase in the diameter of the pancreas and to detect pancreatic cysts, abscesses, or pseudocysts.

Hematocrit and hemoglobin levels are used to monitor the patient for bleeding. Peritoneal fluid, obtained through paracentesis or peritoneal lavage, may contain increased levels of pancreatic enzymes. The stools of patients with pancreatic disease are often bulky, pale, and foul-smelling. Fat content of stools varies between 50% and 90% in pancreatic disease; normally, the fat content is 20%. ERCP is rarely used in the diagnostic evaluation of acute pancreatitis because the patient is acutely ill; however, it may be valuable in the treatment of gallstone pancreatitis.

Medical Management

Management of the patient with acute pancreatitis is directed toward relieving symptoms and preventing or treating complications. All oral intake is withheld to inhibit pancreatic stimulation and secretion of pancreatic enzymes. Parenteral nutrition is usually an important part of therapy, particularly in debilitated patients, because of the extreme metabolic stress associated with acute pancreatitis (Dejong, Greve & Soeters, 2001). Nasogastric suction may be used to relieve nausea and vomiting, to decrease painful abdominal distention and paralytic ileus, and to remove hydrochloric acid so that it does not enter the duodenum and stimulate the pancreas. Histamine-2 (H2) antagonists (eg, cimetidine [Tagamet] and ranitidine [Zantac]) may be prescribed to decrease pancreatic activity by inhibiting HCl secretion.

PAIN MANAGEMENT

Adequate pain medication is essential during the course of acute pancreatitis to provide sufficient pain relief and minimize restlessness, which may stimulate pancreatic secretion further. Morphine and morphine derivatives are often avoided because it has been thought that they cause spasm of the sphincter of Oddi; meperidine (Demerol) is often prescribed because it is less likely to cause spasm of the sphincter (Porth, 2002). Antiemetic agents may be prescribed to prevent vomiting.

INTENSIVE CARE

Correction of fluid and blood loss and low albumin levels is necessary to maintain fluid volume and prevent renal failure. The patient is usually acutely ill and is monitored in the intensive care unit, where hemodynamic monitoring and arterial blood gas monitoring are initiated. Antibiotic agents may be prescribed if infection is present; insulin may be required if significant hyperglycemia occurs.

RESPIRATORY CARE

Aggressive respiratory care is indicated because of the high risk for elevation of the diaphragm, pulmonary infiltrates and effusion, and atelectasis. Hypoxemia occurs in a significant number of patients with acute pancreatitis even with normal x-ray findings. Respiratory care may range from close monitoring of arterial blood gases to use of humidified oxygen to intubation and mechanical ventilation (see Chap. 25 for further discussion).

BILIARY DRAINAGE

Placement of biliary drains (for external drainage) and stents (indwelling tubes) in the pancreatic duct through endoscopy has been performed to reestablish drainage of the pancreas. This has resulted in decreased pain and increased weight gain.

SURGICAL INTERVENTION

Although often risky because the acutely ill patient is a poor surgical risk, surgery may be performed to assist in the diagnosis of pancreatitis (diagnostic laparotomy), to establish pancreatic drainage, or to resect or debride a necrotic pancreas. The patient who undergoes pancreatic surgery may have multiple drains in place postoperatively as well as a surgical incision that is left open for irrigation and repacking every 2 to 3 days to remove necrotic debris (Fig. 40-6).
Postacute Management
Antacids may be used when acute pancreatitis begins to resolve. Oral feedings low in fat and protein are initiated gradually. Caffeine and alcohol are eliminated from the diet. If the episode of pancreatitis occurred during treatment with thiazide diuretics, corticosteroids, or oral contraceptives, these medications are discontinued. Follow-up of the patient may include ultrasound, x-ray studies, or ERCP to determine whether the pancreatitis is resolving and to assess for abscesses and pseudocysts. ERCP may also be used to identify the cause of acute pancreatitis if it is in question and for endoscopic sphincterotomy and removal of gallstones from the common bile duct.

Nursing Process: The Patient with Acute Pancreatitis

Assessment
The health history focuses on the presence and character of the abdominal pain and discomfort. The nurse assesses the presence of pain, its location, its relationship to eating and to alcohol consumption, and the effectiveness of pain relief measures. It also is important to assess the patient’s nutritional and fluid status and history of gallbladder attacks and alcohol use. A history of gastrointestinal problems, including nausea, vomiting, diarrhea, and passage of fatty stools, is elicited. The nurse assesses the abdomen for pain, tenderness, guarding, and bowel sounds, noting the presence of a board-like or soft abdomen. It also is important to assess respiratory status, respiratory rate and pattern, and breath sounds. Normal and adventitious breath sounds and abnormal findings on chest percussion, including dullness at the bases of the lungs and abnormal tactile fremitus, are documented. The nurse assesses the patient’s nutritional and psychological status of the patient and family and their coping, because they are often anxious about the severity of the symptoms and the acuteness of illness.

Diagnosis

Nursing Diagnoses
Based on all the assessment data, the major nursing diagnoses of the patient with acute pancreatitis include the following:

- Acute pain related to inflammation, edema, distention of the pancreas, and peritoneal irritation
- Ineffective breathing pattern related to severe pain, pulmonary infiltrates, pleural effusion, atelectasis, and elevated diaphragm
- Imbalanced nutrition, less than body requirements, related to reduced food intake and increased metabolic demands
- Impaired skin integrity related to poor nutritional status, bed rest, and multiple drains and surgical wound

Collaborative Problems/ Potential Complications
Based on assessment data, potential complications that may occur include the following:

- Fluid and electrolyte disturbances
- Necrosis of the pancreas
- Shock and multiple organ dysfunction

Planning and Goals
The major goals for the patient include relief of pain and discomfort, improved respiratory function, improved nutritional status, maintenance of skin integrity, and absence of complications.

Nursing Interventions

Relieving Pain and Discomfort
Because the pathologic process responsible for pain is autodigestion of the pancreas, the objectives of therapy are to relieve pain and decrease secretion of the enzymes of the pancreas. The pain of acute pancreatitis is often very severe, necessitating the liberal use of analgesic agents. Meperidine (Demerol) is the medication of choice; morphine sulfate is avoided because it causes spasm of the sphincter of Oddi (Porth, 2002). Oral feedings are withheld to decrease the formation and secretion of secretin. The patient is maintained on parenteral fluids and electrolytes to restore and maintain fluid balance. Nasogastric suction is used to remove gastric secretions and to relieve abdominal distention. The nurse provides frequent oral hygiene and care to decrease discomfort from the nasogastric tube and relieve dryness of the mouth.

The acutely ill patient is maintained on bed rest to decrease the metabolic rate and reduce the secretion of pancreatic and gastric enzymes. If the patient experiences increasing severity of pain, the nurse reports this to the physician because the patient may be experiencing hemorrhage of the pancreas, or the dose of analgesic may be inadequate.

The patient with acute pancreatitis often has a clouded sensorium because of severe pain, fluid and electrolyte disturbances, and hypoxia. Therefore, the nurse provides frequent and repeated but simple explanations about the need for withholding fluid intake and about maintenance of gastric suction and bed rest.

Improving Breathing Pattern
The nurse maintains the patient in a semi-Fowler’s position to decrease pressure on the diaphragm by a distended abdomen and to increase respiratory expansion. Frequent changes of position are necessary to prevent atelectasis and pooling of respiratory secretions. Pulmonary assessment and monitoring of pulse oximetry or arterial blood gases are essential to detect changes in respiratory status so that early treatment can be initiated. The nurse instructs the patient in techniques of coughing and deep breathing to improve respiratory function and encourages and assists the patient to cough and deep breathe every 2 hours.

Improving Nutritional Status
The patient with acute pancreatitis is not permitted food and oral fluid intake; however, it is important to assess the patient’s nutritional status and to note factors that alter the patient’s nutritional requirements (eg, temperature elevation, surgery, drainage). Laboratory test results and daily weights are useful in monitoring the nutritional status.

Parenteral nutrition may be prescribed. In addition to administering parenteral nutrition, the nurse monitors serum glucose levels every 4 to 6 hours. As the acute symptoms subside, the nurse gradually reintroduces oral feedings. Between acute attacks, the patient receives a diet high in carbohydrates and low in fat and proteins. The patient should avoid heavy meals and alcoholic beverages.

Improving Skin Integrity
The patient is at risk for skin breakdown because of poor nutritional status, enforced bed rest, and restlessness, which may result in pressure ulcers and breaks in tissue integrity. In addition, the patient who has undergone surgery, has had multiple drains inserted, or has an open surgical incision is at risk for skin breakdown and infection. The nurse carefully assesses the wound,
drainage sites, and skin for signs of infection, inflammation, and breakdown. The nurse carries out wound care as prescribed and takes precautions to protect intact skin from contact with drainage. Consultation with an enterostomal therapist is often helpful in identifying appropriate skin care devices and protocols. It is important to turn the patient every 2 hours; use of specialty beds may be indicated to prevent skin breakdown.

**MONITORING AND MANAGING POTENTIAL COMPLICATIONS**

Fluid and electrolyte disturbances are common complications because of nausea, vomiting, movement of fluid from the vascular compartment to the peritoneal cavity, diaphoresis, fever, and the use of gastric suction. The nurse assesses the patient’s fluid and electrolyte status by noting skin turgor and moistness of mucous membranes. The nurse weighs the patient daily and carefully measures fluid intake and output, including urine output, nasogastric secretions, and diarrhea. In addition, it is important to assess the patient for other factors that may affect fluid and electrolyte status, including increased body temperature and wound drainage. The nurse assesses the patient for ascites and measures abdominal girth daily if ascites is suspected.

Intravenous fluids are administered and may be accompanied by infusion of blood, blood products, and albumin to maintain the blood volume and to prevent or treat hypovolemic shock. It is important to keep emergency medications readily available because of the risk of circulatory collapse and shock. The nurse promptly reports decreased blood pressure and reduced urine output because they may indicate hypovolemia and shock or renal failure. Low serum calcium and magnesium levels may occur and require prompt treatment.

Pancreatic necrosis is a major cause of morbidity and mortality in patients with acute pancreatitis. The patient who develops necrosis is at risk for hemorrhage, septic shock, and multiple organ failure. The patient may undergo diagnostic procedures to confirm pancreatic necrosis; surgical debridement or insertion of multiple drains may be performed. The patient with pancreatic necrosis is usually critically ill and requires expert medical and nursing management, including hemodynamic monitoring in the intensive care unit.

In addition to carefully monitoring vital signs and other signs and symptoms, the nurse is responsible for administering prescribed fluids, medications, and blood products; assisting with supportive management, such as use of a ventilator; preventing additional complications; and attending to the patient’s physical and psychological care.

Shock and multiple organ failure may occur with acute pancreatitis. Hypovolemic shock may occur as a result of hypovolemia and sequestration of fluid in the peritoneal cavity. Hemorrhagic shock may occur with hemorrhagic pancreatitis. Septic shock may occur with bacterial infection of the pancreas. Cardiac dysfunction may occur as a result of fluid and electrolyte disturbances, acid–base imbalances, and release of toxic substances into the circulation.

The nurse closely monitors the patient for early signs of neurologic, cardiovascular, renal, and respiratory dysfunction. The nurse must be prepared to respond quickly to rapid changes in the patient’s status, treatments, and therapies. In addition, it is important to inform the family about the status and progress of the patient and allow them to spend time with the patient. (Management of the patient in shock is discussed in detail in Chap. 15.)

**PROMOTING HOME AND COMMUNITY-BASED CARE**

**Teaching Patients Self-Care**

The patient who has survived an episode of acute pancreatitis has been acutely ill. A prolonged period is needed to regain strength and return to previous level of activity. The patient is often still weak and debilitated weeks or months after an acute episode of pancreatitis. Because of the severity of the acute illness, the patient may not recall many of the explanations and instructions given during the acute phase, so these often need to be repeated and reinforced. The nurse instructs the patient about the factors implicated in the onset of acute pancreatitis and about the need to avoid high-fat foods, heavy meals, and alcohol. It is important to give the patient and family verbal and written instructions about signs and symptoms of acute pancreatitis and possible complications that should be reported promptly to the physician.

If acute pancreatitis is a result of biliary tract disease, such as gallstones and gallbladder disease, additional explanations are needed about required dietary modifications. If the pancreatitis is a result of alcohol abuse, the nurse reminds the patient of the importance of eliminating all alcohol.

**Continuing Care**

A referral for home care often is indicated; this enables the nurse to assess the patient’s physical and psychological status and adherence to the therapeutic regimen. The nurse also assesses the home situation and reinforces instructions about fluid and nutrition intake and avoidance of alcohol.

When the acute attack has subsided, some patients may be inclined to return to their previous drinking habits. The nurse provides specific information about resources and support groups that may be of assistance in avoiding alcohol in the future. Referral to Alcoholics Anonymous or other appropriate support groups is essential. A summary of nursing management of the patient with acute pancreatitis is provided in the Plan of Nursing Care.

**Evaluation**

**EXPECTED PATIENT OUTCOMES**

Expected patient outcomes may include:

1. Reports relief of pain and discomfort
   a. Uses analgesics and anticholinergics as prescribed, without overuse
   b. Maintains bed rest as prescribed
   c. Avoids alcohol to decrease abdominal pain
2. Experiences improved respiratory function
   a. Changes position in bed frequently
   b. Coughs and takes deep breaths at least every hour
   c. Demonstrates normal respiratory rate and pattern, full lung expansion, normal breath sounds
   d. Demonstrates normal body temperature and absence of respiratory infection
3. Achieves nutritional and fluid and electrolyte balance
   a. Reports decrease in number of episodes of diarrhea
   b. Identifies and consumes high-carbohydrate, low-protein foods
   c. Explains rationale for eliminating alcohol intake
   d. Maintains adequate fluid intake within prescribed guidelines
   e. Exhibits adequate urine output

<thead>
<tr>
<th>Nursing Interventions</th>
<th>Rationale</th>
<th>Expected Outcomes</th>
</tr>
</thead>
</table>
| **Nursing Diagnosis:** Acute pain and discomfort related to edema, distention of the pancreas, and peritoneal irritation  
**Goal:** Relief of pain and discomfort | | |
| 1. Administer meperidine (Demerol) frequently, as prescribed, to achieve level of pain acceptable to patient based on patient’s level of pain and discomfort. | Meperidine acts by depressing the central nervous system and thereby increasing the patient’s pain threshold. Morphine is avoided because it produces spasm of the sphincter of Oddi. | • Reports relief of pain  
• Moves and turns without increasing pain and discomfort  
• Rests comfortably and sleeps for increasing periods  
• Reports less frequent episodes of pain, discomfort, and cramping  
• Experiences enhanced pain relief  
• Reports increased feelings of well-being and security with the health care team |
| 2. Using a pain scale, assess pain level before and after administration of analgesic. | Assessment and control of pain are important because restlessness increases body metabolism, which stimulates the secretion of pancreatic and gastric enzymes. | |
| 3. Report unrelieved pain or increasing intensity of pain. | Pain may increase pancreatic enzymes and may also indicate pancreatic hemorrhage. | |
| 4. Assist the patient to assume positions of comfort; turn and reposition every 2 hours. | Frequent turning relieves pressure and assists in preventing pulmonary and vascular complications. | |
| 5. Use nonpharmacologic interventions for relieving pain (eg, relaxation, focused breathing, diversion). | Use of nonpharmacologic methods will enhance the effects of analgesics. Gate control theory states that cutaneous stimulation closes the pain pathways. | |
| 6. Listen to patient’s expression of pain experience. | Demonstration of caring can help to decrease anxiety. | |
| **Goal:** Relief of pain related to stimulation of the pancreas | | |
| 1. Administer anticholinergic medications as prescribed. | Anticholinergic medications reduce gastric and pancreatic secretion. | • Reports relief of pain, discomfort, and abdominal cramping  
• Consumes no fluid and food during acute phase  
• Maintains bed rest  
• Identifies rationale for fluid and dietary restrictions and use of nasogastric drainage  
• Cooperates with insertion of nasogastric tube and suction |
| 2. Withhold oral intake. | Pancreatic secretion is increased by food and fluid intake. | |
| 3. Maintain the patient on bed rest. | Bed rest decreases body metabolism and thus reduces pancreatic and gastric secretions. | |
   a. Measure gastric secretions at specified intervals.  
   b. Observe and record color and viscosity of gastric secretions.  
   c. Ensure that the nasogastric tube is patent to permit free drainage. | Nasogastric suction removes gastric contents and prevents gastric secretions from entering the duodenum and stimulating the secretin mechanism. Decompression of the intestines (if intestinal intubation is used) also assists in relieving respiratory distress. | |
| **Nursing Diagnosis:** Discomfort related to nasogastric tube  
**Goal:** Relief of discomfort associated with nasogastric intubation | | |
| 1. Use water-soluble lubricant around external nares. | Prevents irritation of nares | • Exhibits intact skin and tissue of nares at site of nasogastric tube insertion  
• Reports no pain or irritation of nares or oropharynx  
• Exhibits moist, clean mucous membranes of mouth and nasopharynx  
• States that thirst is relieved by oral hygiene  
• Identifies rationale for nasogastric tube and suction |
| 2. Turn patient at intervals; avoid pressure or tension on nasogastric tube | Relieves pressure of tube on esophageal and gastric mucosa | |
| 3. Provide oral hygiene and gargling solutions without alcohol. | Relieves dryness and irritation of oropharynx | |
| 4. Explain rationale for use of nasogastric drainage. | Assists patient to cooperate with the drainage, nasogastric tube, and suction. | (continued) |

</table>
| **Nursing Diagnosis:** Imbalanced nutrition: less than body requirements related to inadequate dietary intake, impaired pancreatic secretions, increased nutritional needs secondary to acute illness, and increased body temperature  | 1. Alteration in pancreatic secretions interferes with normal digestive processes. Acute illness, infection, and fever increase metabolic needs. | • Maintains normal body weight  
• Demonstrates no additional weight loss  
• Maintains normal serum glucose levels  
• Reports decreasing episodes of vomiting and diarrhea  
• Reports return of normal stool characteristics and bowel pattern  
• Consumes foods high in carbohydrate, low in fat and protein  
• Explains rationale for high-carbohydrate, low-fat, low-protein diet  
• Eliminates alcohol from diet  
• Explains rationale for limiting coffee intake and avoiding spicy foods  
• Participates in Alcoholics Anonymous or other counseling approach  
• Returns to and maintains desirable weight |
| **Goal:** Improvement in nutritional status                                           | 2. Impairment of endocrine function of the pancreas leads to increased serum glucose levels. |                                                                                  |
| 1. Assess current nutritional status and increased metabolic requirements.           | 3. Parenteral administration of fluids, electrolytes, and nutrients is essential to provide fluids, calories, electrolytes, and nutrients when oral intake is prohibited. |                                                                                  |
| 2. Monitor serum glucose levels and administer insulin as prescribed.                | 4. These foods increase caloric intake without stimulating pancreatic secretions beyond the ability of the pancreas to respond. |                                                                                  |
| 3. Administer intravenous fluid and electrolytes and parenteral nutrition as prescribed. | 5. Alcohol intake produces further damage to pancreas and precipitates attacks of acute pancreatitis. |                                                                                  |
| 5. Instruct patient to eliminate alcohol and refer to Alcoholics Anonymous if indicated. | 7. This provides a baseline and a means to measure desirable weight.         |                                                                                  |
| 6. Counsel patient to avoid excessive use of coffee and spicy foods.                 |                                                                          |                                                                                  |
| 7. Monitor daily weights.                                                            |                                                                          |                                                                                  |

**Nursing Diagnosis:** Ineffective breathing pattern related to splinting from severe pain, pulmonary infiltrates, pleural effusion, and atelectasis

**Goal:** Improvement in respiratory function

<table>
<thead>
<tr>
<th>Nursing Interventions</th>
<th>Rationale</th>
<th>Expected Outcomes</th>
</tr>
</thead>
</table>
| 1. Assess respiratory status (rate, pattern, breath sounds), pulse oximetry, and arterial blood gases. | 1. Acute pancreatitis produces retroperitoneal edema, elevation of the diaphragm, pleural effusion, and inadequate lung ventilation. Intra-abdominal infection and labored breathing increase the body’s metabolic demands, which further decreases pulmonary reserve and leads to respiratory failure. | • Demonstrates normal respiratory rate and pattern and full lung expansion  
• Demonstrates normal breath sounds and absence of adventitious breath sounds  
• Demonstrates normal arterial blood gases and pulse oximetry  
• Maintains semi-Fowler’s position when in bed  
• Changes position in bed frequently  
• Coughs and takes deep breaths at least every hour  
• Demonstrates normal body temperature  
• Exhibits no signs or symptoms of respiratory infection or impairment  
• Is alert and responsive to environment |
| 2. Maintain semi-Fowler’s position.                                                   | 2. Decreases pressure on diaphragm and allows greater lung expansion.     |                                                                                  |
| 3. Instruct and encourage patient to take deep breaths and to cough every hour.       | 3. Taking deep breaths and coughing will clear the airways and reduce atelectasis. |                                                                                  |
| 4. Assist patient to turn and change position every 2 hours.                          | 4. Changing position frequently assists aeration and drainage of all lobes of the lungs. |                                                                                  |
| 5. Reduce the excessive metabolism of the body.                                       | 5. Pancreatitis produces a severe peritoneal and retroperitoneal reaction that causes fever, tachycardia, and accelerated respirations. Placing the patient in an air-conditioned room and supporting the patient with oxygen therapy decrease the workload of the respiratory system and the tissue utilization of oxygen. Reduction of fever and pulse rate decreases the metabolic demands on the body. |                                                                                  |
| a. Administer antibiotics as prescribed.                                             |                                                                          |                                                                                  |
| b. Place patient in an air-conditioned room.                                         |                                                                          |                                                                                  |
| c. Administer nasal oxygen as required for hypoxia.                                  |                                                                          |                                                                                  |
| d. Use a hypothermia blanket if necessary.                                           |                                                                          |                                                                                  |

(continued)
**CHRONIC PANCREATITIS**

Chronic pancreatitis is an inflammatory disorder characterized by progressive anatomic and functional destruction of the pancreas. As cells are replaced by fibrous tissue with repeated attacks of pancreatitis, pressure within the pancreas increases. The end result is mechanical obstruction of the pancreatic and common bile ducts and the duodenum. Additionally, there is atrophy of the epithelium of the ducts, inflammation, and destruction of the secreting cells of the pancreas.

Alcohol consumption in Western societies and malnutrition worldwide are the major causes of chronic pancreatitis. Excessive and prolonged consumption of alcohol accounts for approximately 70% of the cases (Clain & Pearson, 1999). The incidence of pancreatitis is 50 times greater in alcoholics than in the nondrinking population. Long-term alcohol consumption causes hypersecretion of protein in pancreatic secretions, resulting in protein plugs and calculi within the pancreatic ducts. Alcohol also has a direct toxic effect on the cells of the pancreas. Damage to these cells is more likely to occur and to be more severe in patients whose diets are poor in protein content and either very high or very low in fat.

**Clinical Manifestations**

Chronic pancreatitis is characterized by recurring attacks of severe upper abdominal and back pain, accompanied by vomiting. Attacks are often so painful that opioids, even in large doses, do not provide adequate relief.
not provide relief. As the disease progresses, recurring attacks of pain are more severe, more frequent, and of longer duration. Some patients experience continuous severe pain; others have a dull, nagging constant pain. The risk of dependence on opioids is increased in pancreatitis because of the chronic nature and severity of the pain.

Weight loss is a major problem in chronic pancreatitis: more than 75% of patients experience significant weight loss, usually caused by decreased dietary intake secondary to anorexia or fear that eating will precipitate another attack. Malabsorption occurs late in the disease, when as little as 10% of pancreatic function remains. As a result, digestion, especially of proteins and fats, is impaired. The stools become frequent, frothy, and foul-smelling because of impaired fat digestion, which results in stools with a high fat content. This is referred to as steatorrhea. As the disease progresses, calcification of the gland may occur, and calcium stones may form within the ducts.

**Assessment and Diagnostic Findings**

ERCP is the most useful study in the diagnosis of chronic pancreatitis. It provides detail about the anatomy of the pancreas and the pancreatic and biliary ducts. It is also helpful in obtaining tissue for analysis and differentiating pancreatitis from other conditions, such as carcinoma. Various imaging procedures, including magnetic resonance imaging, computed tomography, and ultrasound, have been useful in the diagnostic evaluation of patients with suspected pancreatic disorders. Computed tomography scanning or ultrasound is helpful to detect pancreatic cysts.

A glucose tolerance test evaluates pancreatic islet cell function, information necessary for making decisions about surgical resection of the pancreas. An abnormal glucose tolerance test indicative of diabetes may be present. In contrast to the patient with acute pancreatitis, serum amylase levels and the white blood cell count may not be elevated significantly.

**Medical Management**

The management of chronic pancreatitis depends on its probable cause in each patient. Treatment is directed toward preventing and managing acute attacks, relieving pain and discomfort, and managing exocrine and endocrine insufficiency of pancreatitis.

**NONSURGICAL MANAGEMENT**

Nonsurgical approaches may be indicated for the patient who refuses surgery, who is a poor surgical risk, or whose disease and symptoms do not warrant surgical intervention. Endoscopy to remove pancreatic duct stones and stent strictures may be effective in selected patients to manage pain and relieve obstruction. However, such therapy is available only in special centers and is suitable for few patients (Bornman & Beckingham, 2001).

Management of abdominal pain and discomfort is similar to that of acute pancreatitis; however, the focus is usually on the use of nonopioid methods to manage pain. Persistent, unrelieved pain is often the most difficult aspect of management (Bornman & Beckingham, 2001). The physician, nurse, and dietitian emphasize to the patient and family the importance of avoiding alcohol and other foods that the patient has found tend to produce abdominal pain and discomfort. The fact that no other treatment is likely to relieve pain if the patient continues to consume alcohol is stressed to the patient.

Diabetes mellitus resulting from dysfunction of the pancreatic islet cells is treated with diet, insulin, or oral antidiabetic agents. The hazard of severe hypoglycemia with alcohol use is stressed to the patient and family. Pancreatic enzyme replacement is indicated in the patient with malabsorption and steatorrhea (Trolli, Conwell & Zuccaro, 2001).

**SURGICAL MANAGEMENT**

Surgery is generally carried out to relieve abdominal pain and discomfort, restore drainage of pancreatic secretions, and reduce the frequency of acute attacks of pancreatitis. The surgery performed depends on the anatomic and functional abnormalities of the pancreas, including the location of disease within the pancreas, diabetes, exocrine insufficiency, biliary stenosis, and pseudocysts of the pancreas. Other factors taken into consideration in determining whether surgery is to be performed and what procedure is indicated include the patient’s continued use of alcohol and the likelihood that the patient will be able to manage the endocrine or exocrine changes that are expected after surgery.

Pancreaticojejunostomy (also referred to as Roux-en-Y) with a side-to-side anastomosis or joining of the pancreatic duct to the jejunum allows drainage of the pancreatic secretions into the jejunum. Pain relief occurs by 6 months in more than 80% of the patients who undergo this procedure, but pain returns in a substantial number of patients as the disease itself progresses (Tierney et al., 2001).

Other surgical procedures may be performed for different degrees and types of disease, ranging from revision of the sphincter of the ampulla of Vater, to internal drainage of a pancreatic cyst into the stomach (see Pancreatic Cyst discussion), to insertion of a stent, to wide resection or removal of the pancreas. A Whipple resection (pancreatoduodenectomy) has been carried out to relieve the pain of chronic pancreatitis.

Autotransplantation or implantation of the patient’s pancreatic islet cells has been attempted to preserve the endocrine function of the pancreas in patients who have undergone total pancreatectomy. Testing and refinement of this procedure continue in an effort to improve outcomes.

When chronic pancreatitis develops as a result of gallbladder disease, the obstruction is treated by surgery to explore the common duct and remove the stones; usually, the gallbladder is removed at the same time. In addition, an attempt is made to improve the drainage of the common bile duct and the pancreatic duct by dividing the sphincter of Oddi, a muscle that is located at the ampulla of Vater (this surgical procedure is known as a sphincterotomy). A T-tube usually is placed in the common bile duct, requiring a drainage system to collect the bile postoperatively. Nursing care after such surgery is similar to that indicated after other biliary tract surgery.

Patients who undergo surgery for chronic pancreatitis may experience weight gain and improved nutritional status; this may result from reduction in pain associated with eating rather than from correction of malabsorption. However, morbidity and mortality after these surgical procedures are high because of the poor physical condition of the patient before surgery and the concomitant occurrence of cirrhosis. Even after undergoing these surgical procedures, the patient is likely to continue to have pain and impaired digestion secondary to pancreatitis unless alcohol is avoided completely.

**PANCREATIC CYSTS**

As a result of the local necrosis that occurs at the time of acute pancreatitis, collections of fluid may form in the vicinity of the pancreas. These become walled off by fibrous tissue and are called...
pancreatic pseudocysts. They are the most common type of pancreatic cysts. Less common cysts occur as a result of congenital anomalies or are secondary to chronic pancreatitis or trauma to the pancreas.

Diagnosis of pancreatic cysts and pseudocysts is made by ultrasound, computed tomography, and ERCP. ERCP may be used to define the anatomy of the pancreas and evaluate the patency of pancreatic drainage. Pancreatic pseudocysts may be of considerable size. Because of their location behind the posterior peritoneum, when they enlarge they impinge on and displace the stomach or the colon, which are adjacent. Eventually, through pressure or secondary infection, they produce symptoms and require drainage.

Drainage into the gastrointestinal tract or through the skin and abdominal wall may be established. In the latter instance, the drainage is likely to be profuse and destructive to tissue because of the enzyme contents. Hence, steps must be taken to protect the skin near the drainage site from excoriation. Ointments protect the skin if they are applied before excoriation takes place. Another method involves the constant aspiration of digestive secretions from the drainage tract by means of a suction apparatus, so that skin contact with the digestive enzymes is avoided. This method requires expert nursing attention to ensure that the suction tube does not become dislodged and suction is not interrupted. Consultation with an enterostomal therapist is indicated to identify appropriate strategies to maintain drainage and protect the skin.

**CANCER OF THE PANCREAS**

The incidence of pancreatic cancer has decreased slightly over the past 25 years in non-Caucasian men. It is the fifth leading cause of cancer deaths in the United States and occurs most frequently in the fifth to seventh decades of life (American Cancer Society, 2002). Cigarette smoking, exposure to industrial chemicals or toxins in the environment, and a diet high in fat, meat, or both are associated with pancreatic cancer, although their role is not completely clear. The risk for pancreatic cancer increases as the extent of cigarette smoking increases. Diabetes mellitus, chronic pancreatitis, and hereditary pancreatitis are also associated with pancreatic cancer. The pancreas can also be the site of metastasis from other tumors.

Cancer may arise in any portion of the pancreas (in the head, the body, or the tail); clinical manifestations vary depending on the location of the lesion and whether functioning, insulin-secreting pancreatic islet cells are involved. Approximately 75% of pancreatic cancers originate in the head of the pancreas and give rise to a distinctive clinical picture. Functioning islet cell tumors, whether benign (adenoma) or malignant (carcinoma), are responsible for the syndrome of hyperinsulinism. With these exceptions, the symptoms are nonspecific, and patients usually do not seek medical attention until late in the disease; 80% to 85% of patients have advanced, unresectable tumor when first detected. In fact, pancreatic carcinoma has only a 2% to 5% survival rate at 5 years regardless of the stage of disease at diagnosis or treatment (Tierney et al., 2001).

**Clinical Manifestations**

Pain, jaundice, or both are present in more than 90% of patients and, along with weight loss, are considered classic signs of pancreatic carcinoma. However, they often do not appear until the disease is far advanced. Other signs include rapid, profound, and progressive weight loss as well as vague upper or midabdominal pain or discomfort that is unrelated to any gastrointestinal function and is often difficult to describe. Such discomfort radiates as a boring pain in the midback and is unrelated to posture or activity. It is often progressive and severe, requiring the use of opioids. It is often more severe at night. Relief may be obtained by sitting up and leaning forward, or accentuated when lying supine.

Malignant cells from pancreatic cancer are often shed into the peritoneal cavity, increasing the likelihood of metastasis. The formation of ascites is common. An important sign, when present, is the onset of symptoms of insulin deficiency: glucosuria, hyperglycemia, and abnormal glucose tolerance. Thus, diabetes may be an early sign of carcinoma of the pancreas. Meals often aggravate epigastric pain, which usually occurs before the appearance of jaundice and pruritus.

**Assessment and Diagnostic Findings**

Magnetic resonance imaging and computed tomography are used to identify the presence of pancreatic tumors. ERCP is also used in the diagnosis of pancreatic carcinoma. Cells obtained during ERCP are sent to the laboratory for examination. Gastrointestinal x-ray findings may demonstrate deformities in adjacent viscera caused by the impinging pancreatic mass.

Percutaneous fine-needle aspiration biopsy of the pancreas is used to diagnose pancreatic tumors and confirm the diagnosis in patients whose tumors are not resectable, eliminating the stress and postoperative pain of ineffective surgery. In this procedure, a needle is inserted through the anterior abdominal wall into the pancreatic mass, guided by computed tomography, ultrasound, ERCP, or other imaging techniques. The aspirated material is examined for malignant cells. Although percutaneous biopsy is a valuable diagnostic tool, it has some potential drawbacks: a false-negative result if small tumors are missed and seeding of cancer cells along the needle track. Low-dose radiation to the site may be used before the biopsy to reduce the risk of seeding.

Percutaneous transhepatic cholangiography is another procedure that may be performed to identify obstructions of the biliary tract by a pancreatic tumor. Several tumor markers (eg, CA 19-9, CEA, DU-PAN-2) may be used in the diagnostic workup, but they are nonspecific for pancreatic carcinoma. These tumor markers are useful as indicators of disease progression.

Angiography, computed tomography, and laparoscopy may be performed to determine whether the tumor can be removed surgically. Intraoperative ultrasonography has been used to determine if there is metastatic disease to other organs.

**Medical Management**

If the tumor is resectable and localized (typically tumors in the head of the pancreas), the surgical procedure to remove it is usually extensive (see Medical Management in Tumors of the Head of the Pancreas). However, definitive surgical treatment (ie, total excision of the lesion) is often not possible because of the extensive growth when the tumor is finally diagnosed and because of the probable widespread metastases (especially to the liver, lungs, and bones). More often, treatment is limited to palliative measures.

Although pancreatic tumors may be resistant to standard radiation therapy, the patient may be treated with radiation and chemotherapy (fluorouracil and gemcitabine). If the patient undergoes surgery, intraoperative radiation therapy (IORT) may be used to deliver a high dose of radiation to the tumor with minimal injury to other tissues. IORT may also be helpful in relief of
pain. Interstitial implantation of radioactive sources has also been used, although the rate of complications is high. A large biliary stent inserted percutaneously or by endoscopy may be used to relieve jaundice.

**Nursing Management**

Pain management and attention to nutritional requirements are important nursing measures to improve the level of comfort. Skin care and nursing measures are directed toward relief of pain and discomfort associated with jaundice, anorexia, and profound weight loss. Speciality mattresses are beneficial and protect bony prominences from pressure. Pain associated with pancreatic cancer may be severe and may require liberal use of opioids; patient-controlled analgesia should be considered for the patient with severe, escalating pain.

Because of the poor prognosis and likelihood of short survival, end-of-life preferences are discussed and honored. If appropriate, the nurse refers the patient to hospice care. (See Chaps. 16 and 17, respectively, for discussion of care of the patient with cancer and end-of-life care.)

**PROMOTING HOME AND COMMUNITY-BASED CARE**

**Teaching Patients Self-Care.** The specific patient and family teaching indicated varies with the stage of disease and the treatment choices made by the patient. If the patient elects to receive chemotherapy, the nurse focuses teaching on prevention of side effects and complications of the agents used. If surgery is performed to relieve obstruction and establish biliary drainage, teaching addresses management of the drainage system and monitoring for complications. The nurse instructs the family about changes in the patient’s status that should be reported to the physician.

**Continuing Care.** A referral for home care is indicated to help the patient and family deal with the physical problems and discomforts associated with pancreatic cancer and the psychological impact of the disease. The home care nurse assesses the patient’s physical status, fluid and nutritional status, and skin integrity and the adequacy of pain management. The nurse teaches the patient and family strategies to prevent skin breakdown and relieve pain, pruritus, and anorexia. It is important to discuss and arrange palliative care (hospice services) in an effort to relieve patient discomfort, assist with care, and comply with the patient’s end-of-life decisions and wishes.

**TUMORS OF THE HEAD OF THE PANCREAS**

Sixty to eighty percent of pancreatic tumors occur in the head of the pancreas. Tumors in this region of the pancreas obstruct the common bile duct where the duct passes through the head of the pancreas to join the pancreatic duct and empty at the ampulla of Vater into the duodenum. The tumors producing the obstruction may arise from the pancreas, the common bile duct, or the ampulla of Vater.

**Clinical Manifestations**

The obstructed flow of bile produces jaundice, clay-colored stools, and dark urine. Malabsorption of nutrients and fat-soluble vitamins may result from obstruction by the tumor to entry of bile in the gastrointestinal tract. Abdominal discomfort or pain and pruritus may be noted, along with anorexia, weight loss, and malaise. If these signs and symptoms are present, cancer of the head of the pancreas is suspected.

The jaundice of this disease must be differentiated from that due to a biliary obstruction caused by a gallstone in the common duct, which is usually intermittent and appears typically in obese patients, most often women, who have had previous symptoms of gallbladder disease.

**Assessment and Diagnostic Findings**

Diagnostic studies may include duodenography, angiography by hepatic or celiac artery catheterization, pancreatic scanning, percutaneous transhepatic cholangiography, ERCP, and percutaneous needle biopsy of the pancreas. Results of a biopsy of the pancreas may aid in the diagnosis.

**Medical Management**

Before extensive surgery can be performed, a fairly long period of preparation is often necessary because the patient’s nutritional and physical condition is often quite compromised. Various liver and pancreatic function studies are performed. A diet high in protein along with pancreatic enzymes is often prescribed. Preoperative preparation includes adequate hydration, correction of prothrombin deficiency with vitamin K, and treatment of anemia to minimize postoperative complications. Parenteral nutrition and blood component therapy are frequently required.

A biliary-enteric shunt may be performed to relieve the jaundice and, perhaps, to provide time for a thorough diagnostic evaluation. Total pancreatectomy (removal of the pancreas) may be performed if there is no evidence of direct extension of the tumor to adjacent tissues or regional lymph nodes. A pancreaticoduodenectomy (Whipple’s procedure or resection) is used for potentially resectable cancer of the head of the pancreas (Fig. 40-7). This procedure involves removal of the gallbladder, distal portion of the stomach, duodenum, head of the pancreas, and common bile duct and anastomosis of the remaining pancreas and stomach to the jejunum (Stanford, 2001). The result is removal of the tumor, allowing flow of bile into the jejunum. When the tumor cannot be excised, the jaundice may be relieved by diverting the bile flow into the jejunum by anastomosing the jejunum to the gallbladder, a procedure known as cholecystojejunostomy.

The postoperative management of patients who have undergone a pancreatectomy or a pancreaticoduodenectomy is similar to the management of patients after extensive gastrointestinal and biliary surgery. The patient’s physical status is often less than optimal, increasing the risk for postoperative complications. Hemorrhage, vascular collapse, and hepatorenal failure remain the major complications of these extensive surgical procedures. The mortality rate after these procedures has improved because of advances in nutritional support and improved surgical techniques. A nasogastric tube and suction and parenteral nutrition allow the gastrointestinal tract to rest while promoting adequate nutrition.

**Nursing Management**

Preoperatively and postoperatively, nursing care is directed toward promoting patient comfort, preventing complications, and assisting the patient to return to and maintain as normal and comfortable a life as possible. The nurse closely monitors the patient in the intensive care unit after surgery; the patient will have...
multiple intravenous and arterial lines in place for fluid and blood replacement as well as for monitoring arterial pressures, and is on a mechanical ventilator in the immediate postoperative period. It is important to give careful attention to changes in vital signs, arterial blood gases and pressures, pulse oximetry, laboratory values, and urine output. The nurse must also consider the patient’s compromised nutritional status and risk for bleeding. Depending on the type of surgical procedure performed, malabsorption syndrome and diabetes mellitus are likely; the nurse must address these issues during acute and long-term patient care.

Although the patient’s physiologic status is the focus of the health care team in the immediate postoperative period, the patient’s psychological and emotional state must be considered, along with that of the family. The patient has undergone major and risky surgery and is critically ill; thus, anxiety and depression may affect recovery. The immediate and long-term outcome of this extensive surgical resection is uncertain, and the patient and family require emotional support and understanding in the critical and stressful preoperative and postoperative periods.

PROMOTING HOME AND COMMUNITY-BASED CARE

Teaching Patients Self-Care. The patient who has undergone this extensive surgery requires careful and thorough preparation for self-care at home. The nurse instructs the patient and family about the need for modifications in the diet because of malabsorption and hyperglycemia resulting from the surgery. It is important to instruct them about the continuing need for pancreatic enzyme replacement, a low-fat diet, and vitamin supplementation.

The nurse teaches the patient and family strategies to relieve pain and discomfort, along with strategies to manage drains, if present, and to care for the surgical incision. The patient and family members may require instruction about use of patient-controlled analgesia, parenteral nutrition, wound care, skin care, and management of drainage. It is important to describe, verbally and in writing, the signs and symptoms of complications, and to teach the patient and family about indicators of complications that should be reported promptly.

Discharge of the patient to a long-term care setting may be warranted after surgery as extensive as pancreatectomy or pancreaticoduodenectomy, particularly if the patient’s preoperative status was not optimal. Efforts are made to communicate to the long-term care staff about the teaching that has been provided so that instructions can be clarified and reinforced. During the recovery or long-term phase of care, the patient and family receive further instructions about care that they will carry out at home.

Continuing Care. A referral for home care may be indicated when the patient returns home. The home care nurse assesses the patient’s physical and psychological status and the ability of the patient and family to manage needed care. The home care nurse provides needed physical care and monitors the adequacy of pain management. In addition, it is important to assess the patient’s nutritional status and monitor the use of parenteral nutrition. The nurse discusses the use of hospice services with the patient and family and makes a referral if indicated.
PANCREATIC ISLET TUMORS

The pancreas contains the islets (islands) of Langerhans, small nests of cells that secrete directly into the bloodstream and therefore are part of the endocrine system. The hormone insulin is essential for the metabolism of glucose. Diabetes mellitus (see Chap. 41) is the result of deficient secretion of insulin.

At least two types of tumors of the pancreatic islet cells are known: those that secrete insulin (insulinoma) and those in which insulin secretion is not increased (“nonfunctioning” islet cell cancer). Insulinomas produce hypersecretion of insulin and cause an excessive rate of glucose metabolism. The resulting hypoglycemia may produce symptoms of weakness, mental confusion, and seizures. These symptoms may be relieved almost immediately by oral or intravenous administration of glucose. The 5-hour glucose tolerance test is helpful in diagnosing insulinoma and in distinguishing it from other causes of hypoglycemia.

Surgical Management

When a tumor of the islet cells has been diagnosed, surgical treatment with removal of the tumor usually is recommended. The tumors may be benign adenomas or they may be malignant. Complete removal usually results in almost immediate relief of symptoms. In some patients, symptoms may be produced by simple hypertrophy of this tissue rather than a tumor of the islet cells. In such cases, a partial pancreatectomy (removal of the tail and part of the body of the pancreas) is performed.

Nursing Management

In preparing the patient for surgery, the nurse must be alert for symptoms of hypoglycemia and be ready to administer glucose as prescribed if symptoms occur. Postoperatively, the nursing management is the same as that after other upper abdominal surgical procedures, with special emphasis on monitoring serum glucose levels. Patient teaching is determined by the extent of surgery and the alterations in pancreatic function that result.

HYPERINSULINISM

Hyperinsulinism results from overproduction of insulin by the pancreatic islets. Symptoms resemble those of excessive doses of insulin and are attributable to the same mechanism, an abnormal reduction in blood glucose levels. Clinically, it is characterized by episodes during which the patient experiences unusual hunger, nervousness, sweating, headache, and faintness; in severe cases, seizures and episodes of unconsciousness may occur. The findings at the time of surgery or at autopsy may indicate hyperplasia (overgrowth) of the islets of Langerhans or a benign or malignant tumor involving the islets and capable of producing large amounts of insulin (see preceding discussion). Occasionally, tumors of nonpancreatic origin produce an insulin-like material that can cause severe hypoglycemia that may be responsible for seizures coinciding with blood glucose levels too low to sustain normal brain function (ie, below 30 mg/dL [1.6 mmol/L]).

All the symptoms that accompany spontaneous hypoglycemia are relieved by the oral or parenteral administration of glucose. Surgical removal of the hyperplastic or neoplastic tissue from the pancreas is the only successful method of treatment. About 15% of patients with spontaneous or functional hypoglycemia eventually develop diabetes mellitus.

ULCEROGENIC TUMORS

Some tumors of the islets of Langerhans are associated with hypersecretion of gastric acid that produces ulcers in the stomach, duodenum, and jejunum. The result is referred to as Zollinger-Ellison syndrome. The hypersecretion is so great that even after partial gastric resection, enough acid is produced to cause further ulceration. When a marked tendency to develop gastric and duodenal ulcers is noted, an ulcerogenic tumor of the islets of Langerhans is considered.

These tumors, which may be benign or malignant, are treated, when possible, by excision. Frequently, however, because of extension beyond the pancreas, removal is not possible. In many patients, a total gastrectomy may be necessary to reduce the secretion of gastric acid sufficiently to prevent further ulceration.

Critical Thinking Exercises

1. A 48-year-old woman is scheduled for a laparoscopic cholecystectomy. What postoperative care is indicated for this patient? What factors would you consider in preparing her for discharge? How would your care differ if she lived alone? How would you modify teaching for her if she understood little English?

2. A 73-year-old man presents to the emergency department with an oral temperature of 100.6°F, nausea, vomiting of bile, and abdominal distention. He reports mild upper abdominal pain but is not a good historian due to a new onset of mild confusion and lethargy. His sclerae are slightly icteric, blood pressure is 88/50, and heart rate 116 per minute and regular. His primary physician reports fluctuating mild abnormalities in liver function studies over the past 6 months. Considering gerontologic changes in the hepatobiliary system, what diagnostic tests and medical and nursing interventions do you anticipate?

3. A 57-year-old man has a history of alcoholism and cirrhosis. He is admitted to your unit with a diagnosis of acute pancreatitis. He is complaining of severe epigastric pain, vomiting, and diarrhea. What medications and laboratory tests would you expect to see prescribed for this patient? What physical assessment findings will you see? Describe nursing care for this patient, and compare and contrast care with and without the diagnosis of cirrhosis.

4. A 69-year-old woman is being discharged to home with a diagnosis of advanced cancer of the pancreas. She has had a biliary drain inserted to relieve obstruction. What teaching about management of the drainage system is needed for the patient and her family? How would you modify your discharge plans for her if she lives alone and has no family support available?
Assessment and Management of Patients With Diabetes Mellitus

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Differentiate between type 1 and type 2 diabetes.
2. Describe etiologic factors associated with diabetes.
3. Relate the clinical manifestations of diabetes to the associated pathophysiologic alterations.
4. Identify the diagnostic and clinical significance of blood glucose tests.
5. Explain the dietary modifications used for management of people with diabetes.
6. Describe the relationship between diet, exercise, and medication (ie, insulin or oral hypoglycemic agents) for people with diabetes.
7. Develop a plan for teaching insulin self-administration.
8. Identify the role of oral antidiabetic agents in diabetic therapy.
9. Differentiate between hypoglycemia and diabetic ketoacidosis, and hyperosmolar nonketotic syndrome.
10. Describe management strategies for a person with diabetes to use during “sick days.”
11. Describe the major macrovascular, microvascular, and neuropathic complications of diabetes and the self-care behaviors important in their prevention.
12. Identify the teaching aids and community support groups available for people with diabetes.
13. Use the nursing process as a framework for care of the patient with diabetes.
Diabetes mellitus is a group of metabolic diseases characterized by elevated levels of glucose in the blood (hyperglycemia) resulting from defects in insulin secretion, insulin action, or both (American Diabetes Association [ADA], Expert Committee on the Diagnosis and Classification of Diabetes Mellitus, 2003). Normally a certain amount of glucose circulates in the blood. The major sources of this glucose are absorption of ingested food in the gastrointestinal (GI) tract and formation of glucose by the liver from food substances.

Insulin, a hormone produced by the pancreas, controls the level of glucose in the blood by regulating the production and storage of glucose. In the diabetic state, the cells may stop responding to insulin or the pancreas may stop producing insulin entirely. This leads to hyperglycemia, which may result in acute metabolic complications such as diabetic ketoacidosis (DKA) and hyperglycemic hyperosmolar nonketotic syndrome (HHNS). Long-term effects of hyperglycemia contribute to macrovascular complications (coronary artery disease, cerebrovascular disease, and peripheral vascular disease), chronic microvascular complications (kidney and eye disease), and neuropathic complications (diseases of the nerves).

Diabetes mellitus affects about 17 million people, 5.9 million of whom are undiagnosed. In the United States, approximately 800,000 new cases of diabetes are diagnosed yearly (Mokdad et al., 2000). Diabetes is especially prevalent in the elderly, with up to 50% of people older than 65 suffering some degree of glucose intolerance. Among adults in the United States, diagnosed cases of diabetes increased 49% from 1990 to 2000, and similar increases are expected to continue (Centers for Disease Control and Prevention [CDC], 2002).

Minority groups share a disproportionate burden of diabetes compared to non-minority groups. African-Americans and other racial and ethnic groups (Native Americans and persons of Hispanic origin) are more likely than Caucasians to develop diabetes and are at greater risk for many of the complications and higher death rates due to diabetes than Caucasians (U.S. Public Health Service [USPHS], 2000; CDC, 2002). Chart 41-1 summarizes other risk factors for diabetes mellitus.

The far-reaching and devastating physical, social, and economic consequences of diabetes are as follows:

- In the United States, diabetes is the leading cause of non-traumatic amputations, blindness among working-age adults, and end-stage renal disease (USPHS, 2000).
- Diabetes is the third leading cause of death by disease, primarily because of the high rate of cardiovascular disease (myocardial infarction, stroke, and peripheral vascular disease) among people with diabetes.

Glossary

alpha glucosidase inhibitor: a category of oral agents used to treat type 2 diabetes that delay the absorption of carbohydrate, resulting in lower postprandial blood glucose levels

continuous subcutaneous insulin infusion: a small device that delivers insulin on a 24-hour basis as basal insulin; it is also programmed by the patient to deliver a bolus dose before eating a meal in an attempt to mimic normal pancreatic function

diabetes mellitus: a group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both

diabetic ketoacidosis (DKA): a metabolic derangement in type 1 diabetes that results from a deficiency of insulin. Highly acidic ketone bodies are formed, resulting in acidosis; usually requires hospitalization for treatment and is usually caused by nonadherence to the insulin regimen, concurrent illness, or infection.

fasting plasma glucose (FPG): blood glucose determination obtained in the laboratory after fasting for more than 8 hours. Although plasma levels are specified in diagnostic criteria, blood glucose levels, which are slightly higher than plasma levels, are more commonly used.

glycosylated hemoglobin (hemoglobin A1c): a long-term measure of glucose control that is a result of glucose attaching to hemoglobin for the life of the red blood cell (120 days). The goal of diabetes therapy is a normal to near-normal level of glycosylated hemoglobin (referred to as HgbA1c or A1C), the same as in the non diabetic population.

hyperglycemia: elevated blood glucose level—fasting level greater than 110 mg/dL (6.1 mmol/L); 2-hour postprandial level greater than 140 mg/dL (7.8 mmol/L)

hyperglycemic hyperosmolar nonketotic syndrome (HHNS): a metabolic disorder of type 2 diabetes resulting from a relative insulin deficiency initiated by an intercurrent illness that raises the demand for insulin; associated with polyuria and severe dehydration

hypoglycemia: low blood glucose level (less than 60 mg/dL [less than 2.7 mmol/L])

insulin: a hormone secreted by the beta cells of the islets of Langerhans in the pancreas that is necessary for the metabolism of carbohydrates, proteins, and fats; a deficiency of insulin results in diabetes mellitus

impaired fasting glucose (IFG), impaired glucose tolerance (IGT): a metabolic stage intermediate between normal glucose homeostasis and diabetes; not clinical entities in their own right but risk factors for future diabetes and cardiovascular disease

islet cell transplant: an investigational procedure in which purified islet cells from cadaver donors are injected into the portal vein of the liver, with the goal of having these cells secrete insulin and cure type 1 diabetes

ketone: a highly acidic substance formed when the liver breaks down free fatty acids in the absence of insulin. The result is diabetic ketoacidosis.

ketopathy: a long-term complication of diabetes in which the kidney cells are damaged, characterized by microalbuminuria in early stages and progressing to end-stage renal disease

neuropathy: a long-term complication of diabetes resulting from damage to the nerve cell.

retinopathy: a long-term complication of diabetes in which the microvascular system of the eye is damaged

self-monitoring of blood glucose (SMBG): a method of capillary blood glucose testing in which the patient pricks his/her finger and applies a drop of blood to a test strip that is read by a meter

sulfonylurea: a classification of oral anti-diabetic medication for treating type 2 diabetes; enhances insulin secretion and insulin action

thiazolidinediones: a class of oral anti-diabetic medications that reduce insulin resistance in target tissues, enhancing insulin action without directly stimulating insulin secretion

type 1 diabetes: a metabolic disorder characterized by an absence of insulin production and secretion from autoimmune destruction of the beta cells of the islets of Langerhans in the pancreas. Formerly called insulin-dependent, juvenile or type I diabetes.

type 2 diabetes: a metabolic disorder characterized by the relative deficiency of insulin production and a decreased insulin action and increased insulin resistance. Formerly called non-insulin-dependent, adult-onset, or type II diabetes.
Chapter 41  Assessment and Management of Patients With Diabetes Mellitus

There are several different types of diabetes mellitus; they may differ in cause, clinical course, and treatment. The major classifications of diabetes are:

- **Type 1 diabetes** (previously referred to as insulin-dependent diabetes mellitus)
- **Type 2 diabetes** (previously referred to as non-insulin-dependent diabetes mellitus)
- Gestational diabetes mellitus (ADA, Expert Committee on the Diagnosis and Classification of Diabetes Mellitus, 2003)
- Diabetes mellitus associated with other conditions or syndromes

There are several different types of diabetes mellitus; they may differ in cause, clinical course, and treatment. The major classifications of diabetes are:

- **Type 1 diabetes** (previously referred to as insulin-dependent diabetes mellitus)
- **Type 2 diabetes** (previously referred to as non-insulin-dependent diabetes mellitus)
- Gestational diabetes mellitus (ADA, Expert Committee on the Diagnosis and Classification of Diabetes Mellitus, 2003)
- Diabetes mellitus associated with other conditions or syndromes

**Classification of Diabetes**

There are several different types of diabetes mellitus; they may differ in cause, clinical course, and treatment. The major classifications of diabetes are:

- **Type 1 diabetes** (previously referred to as insulin-dependent diabetes mellitus)
- **Type 2 diabetes** (previously referred to as non-insulin-dependent diabetes mellitus)

**OVERVIEW**

The terms “insulin-dependent diabetes” and “non-insulin-dependent diabetes” and their acronyms (IDDM and NIDDM, respectively) are no longer used because they have resulted in classification of patients on the basis of the treatment of their diabetes rather than the underlying etiology. Use of Roman numerals (type I and type II) to distinguish between the two types has been changed to type 1 and type 2 to reduce confusion (ADA, Expert Committee on the Diagnosis and Classification of Diabetes Mellitus, 2003).

Approximately 5% to 10% of people with diabetes have type 1 diabetes, in which the insulin-producing pancreatic beta cells are destroyed by an autoimmune process. As a result, they produce little or no insulin and require insulin injections to control their blood glucose levels. Type 1 diabetes is characterized by an acute onset, usually before age 30 (CDC, Diabetes Surveillance, 1999).

Approximately 90% to 95% of people with diabetes have type 2 diabetes (CDC, Data Factsheet, 2002), which results from decreased sensitivity to insulin (called insulin resistance) and impaired beta cell functioning resulting in decreased insulin production (Quinn, 2001a). Type 2 diabetes is first treated with diet and exercise. If elevated glucose levels persist, diet and exercise are supplemented with oral hypoglycemic agents. In some individuals with type 2 diabetes, oral agents do not control hyperglycemia, and insulin injections are required. In addition, some individuals whose type 2 diabetes can usually be controlled with diet, exercise, and oral agents may require insulin injections during periods of acute physiologic stress (eg, illness or surgery). Type 2 diabetes occurs more among people who are older than 30 years and obese (Diabetes Information Clearing House, 2001).

Diabetes complications may develop in any person with type 1 or type 2 diabetes, not only in patients who take insulin. Some patients with type 2 diabetes who are treated with oral medications may have the impression that they do not really have diabetes or that they simply have “borderline” diabetes. They may believe that, compared with diabetic patients who require insulin injections, their diabetes is not a serious problem. It is important for the nurse to emphasize to these individuals that they do have diabetes and not a borderline problem with sugar (glucose). Borderline diabetes is classified as impaired glucose tolerance (IGT) or impaired fasting glucose (IFG) and refers to a condition in which blood glucose levels fall between normal levels and levels considered diagnostic for diabetes.

Table 41-1 summarizes the major classifications of diabetes, current terminology, old labels, and major clinical characteristics. This classification system is dynamic in two ways. First, research findings suggest many differences among individuals within each category. Second, except for those with type 1 diabetes, patients may move from one category to another. For example, a woman with gestational diabetes may, after delivery, move into the type 2 category. These types also differ in their etiology, clinical course, and management.

**PHYSIOLOGY AND PATHOPHYSIOLOGY OF DIABETES**

Insulin is secreted by beta cells, which are one of four types of cells in the islets of Langerhans in the pancreas. Insulin is an anabolic, or storage, hormone. When a person eats a meal, insulin secretion increases and moves glucose from the blood into muscle, liver, and fat cells. In those cells, insulin:

- Transports and metabolizes glucose for energy
- Stimulates storage of glucose in the liver and muscle (in the form of glycogen)
- Signals the liver to stop the release of glucose
- Enhances storage of dietary fat in adipose tissue
- Accelerates transport of amino acids (derived from dietary protein) into cells

Insulin also inhibits the breakdown of stored glucose, protein, and fat.

During fasting periods (between meals and overnight), the pancreas continuously releases a small amount of insulin (basal

</tbody>
</table>
insulin); another pancreatic hormone called glucagon (secreted by the alpha cells of the islets of Langerhans) is released when blood glucose levels decrease and stimulate the liver to release stored glucose. The insulin and the glucagon together maintain a constant level of glucose in the blood by stimulating the release of glucose from the liver.

Initially, the liver produces glucose through the breakdown of glycogen (glycogenolysis). After 8 to 12 hours without food, the liver forms glucose from the breakdown of noncarbohydrate substances, including amino acids (gluconeogenesis).

**TYPE 1 DIABETES**

Type 1 diabetes is characterized by destruction of the pancreatic beta cells. It is thought that combined genetic, immunologic, and possibly environmental (eg, viral) factors contribute to beta cell destruction. Although the events that lead to beta cell destruction are not fully understood, it is generally accepted that a genetic susceptibility is a common underlying factor in the development of type 1 diabetes. People do not inherit type 1 diabetes itself; rather, they inherit a genetic predisposition, or tendency, toward developing type 1 diabetes. This genetic tendency has been found in people with certain HLA (human leukocyte antigen) types. HLA refers to a cluster of genes responsible for transplantation antigens and other immune processes. About 95% of Caucasians with type 1 diabetes exhibit specific HLA types (DR3 or DR4). The risk of developing type 1 diabetes is increased three to five times in people who have one of these two HLA types. The risk increases 10 to 20 times in people who have both DR3 and DR4 HLA types (as compared with the general population). Immune-mediated diabetes commonly develops during childhood and adolescence, but it can occur at any age (ADA, Expert Committee on the Diagnosis and Classification of Diabetes Mellitus, 2003).

There is also evidence of an autoimmune response in type 1 diabetes. This is an abnormal response in which antibodies are directed against normal tissues of the body, responding to these tissues as if they are foreign. Autoantibodies against islet cells and against endogenous (internal) insulin have been detected in people at the time of diagnosis and even several years before the development of clinical signs of type 1 diabetes. In addition to genetic and immunologic components, environmental factors, such as viruses or toxins, that may initiate destruction of the beta cell are being investigated.

Regardless of the specific etiology, the destruction of the beta cells results in decreased insulin production, unchecked glucose production by the liver, and fasting hyperglycemia. In addition, glucose derived from food cannot be stored in the liver but instead remains in the bloodstream and contributes to postprandial (after meals) hyperglycemia. If the concentration of glucose in the blood exceeds the renal threshold for glucose, usually 180 to 200 mg/dL (9.9 to 11.1 mmol/L), the kidneys may not reabsorb all of the filtered glucose; the glucose then appears in the urine (glucosuria). When excess glucose is excreted in the urine, it is accompanied by excessive loss of fluids and electrolytes. This is called osmotic diuresis.

Because insulin normally inhibits glycogenolysis (breakdown of stored glucose) and gluconeogenesis (production of new glucose from amino acids and other substrates), in people with insulin deficiency, these processes occur in an unrestrained fashion and contribute further to hyperglycemia. In addition, fat breakdown occurs, resulting in an increased production of ketone bodies, which are the byproducts of fat breakdown.

**TYPE 2 DIABETES**

The two main problems related to insulin in type 2 diabetes are insulin resistance and impaired insulin secretion. Insulin resistance refers to a decreased tissue sensitivity to insulin. Normally, insulin binds to special receptors on cell surfaces and initiates a series of reactions involved in glucose metabolism. In type 2 diabetes, these intracellular reactions are diminished, thus rendering insulin less effective at stimulating glucose uptake by the tissues and at regulating glucose release by the liver (Fig. 41-1). The exact mechanisms that lead to insulin resistance and impaired insulin secretion in type 2 diabetes are unknown, although genetic factors are thought to play a role.

To overcome insulin resistance and to prevent the buildup of glucose in the blood, increased amounts of insulin must be secreted to maintain the glucose level at a normal or slightly elevated level. However, if the beta cells cannot keep up with the increased demand for insulin, the glucose level rises, and type 2 diabetes develops.

Despite the impaired insulin secretion that is characteristic of type 2 diabetes, there is enough insulin present to prevent the breakdown of fat and the accompanying production of ketone bodies. Therefore, DKA does not typically occur in type 2 diabetes. Uncontrolled type 2 diabetes may, however, lead to another acute problem, HHNS (see later discussion).
Type 2 diabetes occurs most commonly in people older than 30 years who are obese, although its incidence is increasing in younger adults (CDC, Diabetes Surveillance, 2002). Because it is associated with a slow (over years), progressive glucose intolerance, the onset of type 2 diabetes may go undetected for many years. If symptoms are experienced, they are frequently mild and may include fatigue, irritability, polyuria, polydipsia, skin wounds that heal poorly, vaginal infections, or blurred vision (if glucose levels are very high).

For most patients (approximately 75%), type 2 diabetes is detected incidentally (eg, when routine laboratory tests or ophthalmoscopic examinations are performed). One consequence of undetected diabetes is that long-term diabetes complications (eg, eye disease, peripheral neuropathy, peripheral vascular disease) may have developed before the actual diagnosis of diabetes is made (ADA, Expert Committee on the Diagnosis and Classification of Diabetes Mellitus, 2003).

Because insulin resistance is associated with obesity, the primary treatment of type 2 diabetes is weight loss. Exercise is also important in enhancing the effectiveness of insulin. Oral antidiabetic agents may be added if diet and exercise are not successful in controlling blood glucose levels. If maximum doses of a single category of oral agents fail to reduce glucose levels to satisfactory levels, additional oral agents may be used. Insulin may be added to oral agent therapy, or patients may move to insulin therapy entirely. Some patients require insulin on an ongoing basis, and others may require insulin on a temporary basis during periods of acute physiologic stress, such as illness or surgery.

A recent report has demonstrated that type 2 diabetes can be prevented or delayed in persons at high risk for the disease through weight reduction and increased participation in moderate exercise (Diabetes Prevention Program Research Group, 2002). Metformin, one of the antidiabetic agents, also prevented or delayed the onset of type 2 diabetes, but to a lesser degree. The findings of this study support the role that weight reduction and exercise have in the prevention of type 2 diabetes (Chart 41-2).

**GESTATIONAL DIABETES**

Gestational diabetes is any degree of glucose intolerance with its onset during pregnancy. Hyperglycemia develops during pregnancy because of the secretion of placental hormones, which causes insulin resistance. For women who meet one or more of the following criteria, selective screening for diabetes during pregnancy is now being recommended between the 24th and 28th weeks of gestation: age 25 years or older; age 25 years or younger and obese; family history of diabetes in first-degree relatives; or member of an ethnic/racial group with a high prevalence of diabetes (eg, Hispanic American, Native American, Asian American, African American, or Pacific Islander).

Gestational diabetes occurs in up to 14% of pregnant women and increases their risk for hypertensive disorders during pregnancy (ADA, Gestational Diabetes Mellitus, 2003). Initial management includes dietary modification and blood glucose monitoring. If hyperglycemia persists, insulin is prescribed. Oral antidiabetic agents should not be used during pregnancy. Goals for blood glucose levels during pregnancy are 105 mg/dL (5.8 mmol/L) or less before meals and 120 mg/dL (6.7 mmol/L) or less 2 hours after meals (ADA, Gestational Diabetes Mellitus, 2003).

After delivery of the infant, blood glucose levels in the woman with gestational diabetes return to normal. However, many women who have had gestational diabetes develop type 2 diabetes later in life. Therefore, all women who have had gestational diabetes should be counseled to maintain their ideal body weight and to exercise regularly to reduce their risk for type 2 diabetes (ADA, Gestational Diabetes Mellitus, 2003).

**CLINICAL MANIFESTATIONS**

Clinical manifestations of all types of diabetes include the “three Ps”: polyuria, polydipsia, and polyphagia. Polyuria (increased urination) and polydipsia (increased thirst) occur as a result of the excess loss of fluid associated with osmotic diuresis. The patient also experiences polyphagia (increased appetite) resulting from the catabolic state induced by insulin deficiency and the breakdown of proteins and fats. Other symptoms include fatigue and weakness, sudden vision changes, tingling or numbness in hands or feet, dry skin, skin lesions or wounds that are slow to heal, and recurrent infections. The onset of type 1 diabetes may also be associated with sudden weight loss or nausea, vomiting, or abdominal pains, if DKA has developed.

**ASSESSMENT AND DIAGNOSTIC FINDINGS**

An abnormally high blood glucose level is the basic criterion for the diabetes diagnosis. Fasting plasma glucose (FPG) levels of 126 mg/dL (7.0 mmol/L) or more or random plasma glucose levels exceeding 200 mg/dL (11.1 mmol/L) on more than one occasion are diagnostic of diabetes. The oral glucose tolerance test and the intravenous glucose tolerance test are no longer recommended for routine clinical use. See Chart 41-3 for the ADA’s diagnostic criteria for diabetes mellitus (ADA, Expert Committee on the Diagnosis and Classification of Diabetes Mellitus, 2003).

Plasma glucose values may be 10% to 15% higher than whole blood values, which are obtained with finger sticks (Porth, 2002). In addition to the assessment and diagnostic evaluation performed to diagnose diabetes, ongoing specialized assessment of patients with known diabetes and evaluation for complications in patients with newly diagnosed diabetes are important components of care. Parameters that should be regularly assessed are discussed in Chart 41-4.
What causes age-related changes in carbohydrate metabolism is unresolved. Possibilities include poor diet, physical inactivity, a decrease in the lean body mass in which ingested carbohydrate may be stored, altered insulin secretion, and increase in fat tissue, which increases insulin resistance.

Diabetes Management

The main goal of diabetes treatment is to normalize insulin activity and blood glucose levels to reduce the development of vascular and neuropathic complications. The importance of tight blood glucose control was demonstrated by the Diabetes Control and Complications Trial (DCCT), a 10-year prospective clinical trial conducted from 1983 to 1993. The trial investigated the impact of intensive glucose control on the development and progression of complications such as retinopathy, nephropathy, and neuropathy. A cohort of 1,441 people with type 1 diabetes were randomly assigned to conventional treatment (one or two insulin injections per day) or intensive treatment (three or four insulin injections per day or insulin pump therapy plus frequent blood glucose monitoring and weekly contacts with diabetes educators). Results demonstrated that the risk for developing retinopathy, nephropathy, and early signs of nephropathy (microalbuminuria and albuminuria) was dramatically reduced. The reduction was attributed to control of blood glucose levels to normal or near-normal levels. The ADA now recommends that all patients with diabetes strive for glucose control to reduce their risks for complications (ADA, Implications of the Diabetes Control and Complications Trial, 2003).

The major adverse effect of intensive therapy was a threefold increase in the incidence of severe hypoglycemia (severe enough to require assistance from another person), coma, or seizure. Because of these adverse effects, intensive therapy must be initiated with caution and must be accompanied by thorough education of the patient and family and by responsible behavior of the patient. Careful screening of patients is a key step in initiating intensive therapy.
A study conducted in the United Kingdom and reported in 1998 supported the results of the DCCT in type 2 diabetes and demonstrated a decrease in complications in patients with type 2 diabetes receiving intensive therapy compared to those receiving conventional therapy (United Kingdom Prospective Diabetes Study Group [UKPDS], 1998; ADA, Implications of the United Kingdom Prospective Diabetes Study, 2003).

Therefore, the therapeutic goal for diabetes management is to achieve normal blood glucose levels (euglycemia) without hypoglycemia and without seriously disrupting the patient’s usual lifestyle and activity. There are five components of diabetes management (Fig. 41-2):

- Nutritional management
- Exercise
- Monitoring
- Pharmacologic therapy
- Education

Treatment varies because of changes in lifestyle and physical and emotional status as well as advances in treatment methods. Therefore, diabetes management involves constant assessment and modification of the treatment plan by health professionals and daily adjustments in therapy by the patient. Although the health care team directs the treatment, it is the patient who must manage the complex therapeutic regimen. For this reason, patient and family education is an essential component of diabetes treatment and is as important as all other components of the regimen.

NUTRITIONAL MANAGEMENT

Nutrition, diet, and weight control are the foundation of diabetes management. The most important objective in the dietary and nutritional management of diabetes is control of total caloric intake to attain or maintain a reasonable body weight and control of blood glucose levels. Success of this alone is often associated with reversal of hyperglycemia in type 2 diabetes. However, achieving this goal is not always easy. Because nutritional management of diabetes is so complex, a registered dietitian who understands diabetes management has the major responsibility for this aspect of the therapeutic plan. However, the nurse and all other members of the health care team need to be knowledgeable about nutritional therapy and supportive of the patient who needs to implement dietary and lifestyle changes (ADA, Expert Committee on the Diagnosis and Classification of Diabetes Mellitus, 2003). Nutritional management of the diabetic patient includes the following goals (ADA, Evidence-Based Nutrition Principles and Recommendations for the Treatment and Prevention of Diabetes and Related Complications, 2003):

- Providing all the essential food constituents (eg, vitamins, minerals) necessary for optimal nutrition
- Meeting energy needs
- Achieving and maintaining a reasonable weight
- Preventing wide daily fluctuations in blood glucose levels, with blood glucose levels as close to normal as is safe and practical to prevent or reduce the risk for complications
- Decreasing serum lipid levels, if elevated, to reduce the risk for macrovascular disease

For patients who require insulin to help control blood glucose levels, maintaining as much consistency as possible in the amount of calories and carbohydrates ingested at different meal times is essential. In addition, consistency in the approximate time intervals between meals, with the addition of snacks if necessary, helps in preventing hypoglycemic reactions and in maintaining overall blood glucose control.

For obese diabetic patients (especially those with type 2 diabetes), weight loss is the key to treatment. (It is also a major factor in preventing diabetes.) In general, overweight is considered to be a body mass index (BMI) of 25 to 29; obesity is defined as 20% above ideal body weight or a BMI equal to or greater than 30 (National Institutes of Health, 2000). BMI is a weight-to-height ratio calculated by dividing body weight (in kilograms) by the square of the height (in meters). Calculation of BMI is discussed in Chapter 5. Obesity is associated with an increased resistance to insulin; it is also a main factor in type 2 diabetes. Some obese patients who have type 2 diabetes and who require insulin or oral agents to control blood glucose levels may be able to reduce or eliminate the need for medication through weight loss. A weight loss as small as 10% of total weight may significantly improve blood glucose levels. For obese diabetic patients who do not take insulin, consistent meal content or timing is not as critical. Rather, decreasing the overall caloric intake assumes more importance. However, meals should not be skipped. Pacing food intake throughout the day places more manageable demands on the pancreas.

Long-term adherence to the meal plan is one of the most challenging aspects of diabetes management. For obese patients, it may be more realistic to restrict calories only moderately. For those who have lost weight, maintaining the weight loss may be difficult. To help these patients incorporate new dietary habits into their lifestyles, diet education, behavioral therapy, group support, and ongoing nutrition counseling are encouraged.

MEAL PLANNING AND RELATED TEACHING

For all patients with diabetes, the meal plan must consider the patient’s food preferences, lifestyle, usual eating times, and ethnic and cultural background. For patients using intensive insulin therapy, there may be greater flexibility in the timing and content of meals by allowing adjustments in insulin dosage for changes in eating and exercise habits. Advances in insulin management (new
NURSING RESEARCH PROFILE 41-1
Diabetes Mismanagement in Adolescents and Young Adults

**Purpose**
Adolescence and young adulthood are periods often associated with health-compromising behaviors. This study was conducted to determine the relationship between health-compromising behavior, age, gender, and diabetes mismanagement in adolescents and young adults.

**Study Sample and Design**
A correlational study was conducted; the sample included 107 adolescents and young adults with type 1 diabetes. Health-compromising behavior was measured by a 10-item Problem Behavior Survey that assessed subjects’ involvement with hard drugs, marijuana, alcohol, smoking/chewing tobacco, physical violence, fighting, carrying weapons, riding with a drinking driver, driving while drinking, and having sexual intercourse. Higher scores indicate higher levels of health-compromising behavior. Diabetes mismanagement was measured using a 6-item questionnaire that addressed glucose monitoring, diet, and insulin administration for the previous 10 days. Higher scores indicate higher levels of diabetes mismanagement. HgbA1c levels were used as indicators of metabolic control. The mean age of the sample was 17.4 (SD ± 3.2); their ages ranged from 12 to 24 years. It was largely a Caucasian sample. Age since diagnosis of diabetes was 7 years and 5 months. Subjects reported a mean daily insulin dose of 1.0 units per kilogram of body weight. The mean HgbA1c of the sample was 8.9%. HgbA1c values ranged from 5.1% to 16.6%; the normal range of HgbA1c was 3.4% to 6.2%.

**Findings**
The mean scores on the diabetes management scale and the health-compromising scale were below the medians and indicated relatively low levels of diabetes mismanagement and health-compromising behaviors, respectively. Participants were categorized into two groups by scores on the health-compromising scale: those involved in health-compromising behavior and those not involved in such behavior. On multiple regression analysis, correlations were found of diabetes mismanagement with age (r = 0.23, p = 0.05), female gender (r = 0.24, p = 0.05), and participation in health-compromising behaviors (r = 0.32, p = 0.001). Additionally, there was a significant relationship (r = 0.66, p = 0.001) between age and health-compromising behavior. Further analyses revealed that being female and having greater health-compromising behavior contributed to diabetes mismanagement; female subjects were found to have poorer metabolic control than males.

**Nursing Implications**
The results of this study reveal some issues important to nurses involved in the care of adolescents and young adults with type 1 diabetes. Participation in health-compromising behavior and gender are two of the many factors that affect diabetes management and metabolic control. Assessment of health-compromising behavior and diabetes mismanagement should be considered in nurses’ assessment of adolescents and young adults with diabetes. Differentiating those adolescents and young adults who are involved in health-compromising behaviors and those who are not involved in those behaviors may provide information about those at risk for difficulty associated with management of diabetes. It is important to maintain open communication to determine if health-compromising behaviors are being practiced and to discuss these behaviors in a nonjudgmental way to decrease the risk for diabetes mismanagement.

**CALORIC REQUIREMENTS**
Calorie-controlled diets are planned by first calculating the individual’s energy needs and caloric requirements based on the patient’s age, gender, height, and weight. An activity element is then factored in to provide the actual number of calories required for weight maintenance. To promote a 1- to 2-pound weight loss per week, 500 to 1,000 calories are subtracted from the daily total. The calories are distributed into carbohydrates, proteins, and fats, and a meal plan is then developed.

The 1995 Exchange Lists for Meal Planning (ADA, 1995) are presented to the patient using the appropriate amount of calories, with strict diet adherence as the goal. Unfortunately, calorie-controlled diets are often confusing and difficult to comply with. They require patients to measure precise portions and to eat specific foods and amounts at each meal and snack. In this instance, developing a meal plan based on the individual’s usual eating habits and lifestyle may be a more realistic approach to glucose control and weight loss or weight maintenance. In both instances, the patient needs to work closely with a registered dietitian to assess current eating habits and to achieve realistic, individualized goals. The priority for a young patient with type 1 diabetes, for example, should be a diet with enough calories to maintain normal growth and development. Some patients may be underweight at the onset of type 1 diabetes because of rapid weight loss from severe hyperglycemia. The goal with these patients initially may be to provide a higher-calorie diet to regain lost weight.
CALORIC DISTRIBUTION
A diabetic meal plan also focuses on the percentage of calories to come from carbohydrates, proteins, and fats. In general, carbohydrate foods have the greatest effect on blood glucose levels because they are more quickly digested than other foods and are converted into glucose rapidly. Several decades ago it was recommended that diabetic diets contain more calories from protein and fat foods than from carbohydrates to reduce postprandial increases in blood glucose levels. However, this resulted in a dietary intake inconsistent with the goal of reducing the cardiovascular disease commonly associated with diabetes (ADA, Evidence-Based Nutrition Principles and Recommendations for the Treatment and Prevention of Diabetes and Related Complications, 2003).

Carbohydrates. The caloric distribution currently recommended is higher in carbohydrates than in fat and protein. However, research into the appropriateness of a higher-carbohydrate diet in patients with decreased glucose tolerance is ongoing, and recommendations may change accordingly. Currently, the ADA and the American Dietetic Association recommend that for all levels of caloric intake, 50% to 60% of calories should be derived from carbohydrates, 20% to 30% from fat, and the remaining 10% to 20% from protein. These recommendations are also consistent with those of the American Heart Association, American Cancer Society, and the U.S. Department of Agriculture (2000).

Carbohydrates consist of sugars and starches. Little scientific evidence supports the belief that sugars, such as sucrose, promote a greater blood glucose level compared to starches (eg, rice, pasta, or bread). Although low glycemic index diets (described below) may reduce postprandial glucose levels, there seem to be no clear effects on outcomes (ADA, Expert Committee on the Diagnosis and Classification of Diabetes Mellitus, 2003). Thus, the latest nutrition guidelines recommend that all carbohydrates be eaten in moderation to avoid high postprandial blood glucose levels (ADA, Exchange Lists for Meal Planning, 1995). Foods high in carbohydrates, such as sucrose, are not eliminated from the diet but should be eaten in moderation (up to 10% of total calories) because these foods are typically high in fat and lack vitamins, minerals, and fiber.

Carbohydrate counting is another nutritional tool used for blood glucose management because carbohydrates are the main nutrients in food that influence blood glucose levels. This method provides flexibility in food choices, can be less complicated to understand than the diabetic food exchange list, and allows more accurate management with multiple daily injections (insulin before each meal). However, if carbohydrate counting is not used with other meal-planning techniques, weight gain can result. A variety of methods are used to count carbohydrates. When developing a diabetic meal plan using carbohydrate counting, all food sources should be considered. Once digested, 100% of carbohydrates are converted to glucose. However, approximately 50% of protein foods (meat, fish, and poultry) are also converted to glucose.

One method of carbohydrate counting includes counting grams of carbohydrates. If target goals are not reached by counting carbohydrates alone, protein will be factored into the calculations. This is especially true if the meal consists of only meat, fish, and non-starchy vegetables.

An alternative to counting grams of carbohydrate is measuring servings or choices. This method is used more often by people with type 2 diabetes. It is similar to the food exchange list and emphasizes portion control of total servings of carbohydrate at meals and snacks. One carbohydrate serving is equivalent to 15 g of carbohydrate. Examples of one serving are an apple 2 inches in diameter and one slice of bread. Vegetables and meat are counted as one third of a carbohydrate serving.

Although carbohydrate counting is now commonly used for blood glucose management with type 1 and type 2 diabetes, it is not a perfect system. All carbohydrates, to some extent, affect the blood glucose to different degrees, regardless of equivalent serving size.

Fats. The recommendations regarding fat content of the diabetic diet include both reducing the total percentage of calories from fat sources to less than 30% of the total calories and limiting the amount of saturated fats to 10% of total calories. Additional recommendations include limiting the total intake of dietary cholesterol to less than 300 mg/day. This approach may help to reduce risk factors such as elevated serum cholesterol levels, which are associated with the development of coronary artery disease, the leading cause of death and disability among people with diabetes.

The meal plan may include the use of some nonanimal sources of protein (eg, legumes and whole grains) to help reduce saturated fat and cholesterol intake. In addition, the amount of protein intake may be reduced in patients with early signs of renal disease.

Fiber. The use of fiber in diabetic diets has received increased attention as researchers study the effects on diabetes of a high-carbohydrate, high-fiber diet. This type of diet plays a role in lowering total cholesterol and low-density lipoprotein cholesterol in the blood. Increasing fiber in the diet may also improve blood glucose levels and decrease the need for exogenous insulin.

There are two types of dietary fibers: soluble and insoluble. Soluble fiber—in foods such as legumes, oats, and some fruits—plays more of a role in lowering blood glucose and lipid levels than does insoluble fiber, although the clinical significance of this effect is probably small (ADA, Expert Committee on the Diagnosis and Classification of Diabetes Mellitus, 2003). Soluble fiber is thought to be related to the formation of a gel in the GI tract. This gel slows stomach emptying and the movement of food through the upper digestive tract. The potential glucose-lowering effect of fiber may be caused by the slower rate of glucose absorption from foods that contain soluble fiber. Insoluble fiber is found in whole-grain breads and cereals and in some vegetables. This type of fiber plays more of a role in increasing stool bulk and preventing constipation. Both insoluble and soluble fibers increase satiety, which is helpful for weight loss.

One risk involved in suddenly increasing fiber intake is that it may require adjusting the dosage of insulin or oral agents to prevent hypoglycemia. Other problems may include abdominal fullness, nausea, diarrhea, increased flatulence, and constipation if fluid intake is inadequate. If fiber is added to or increased in the meal plan, it should be done gradually and in consultation with a dietitian. The 1995 Exchange Lists for Meal Planning (ADA, 1995) is an excellent guide for increasing fiber intake. Fiber-rich food choices within the vegetable, fruit, and starch/bread exchanges are highlighted in the lists.

FOOD CLASSIFICATION SYSTEMS
To teach diet principles and to help patients in meal planning, several systems have been developed in which foods are organized into groups with common characteristics, such as number of calories, composition of foods (ie, amount of protein, fat, or carbohydrate in the food), or effect on blood glucose levels.

Exchange Lists. A commonly used tool for nutritional management is the Exchange Lists for Meal Planning (ADA, 1995).
There are six main exchange lists: bread/starch, vegetable, milk, meat, fruit, and fat. Foods included on one list (in the amounts specified) contain equal numbers of calories and are approximately equal in grams of protein, fat, and carbohydrate. Meal plans (tailored to the patient’s needs and preferences) are based on a recommended number of choices from each exchange list. Foods on one list may be interchanged with one another, allowing the patient to choose a variety while maintaining as much consistency as possible in the nutrient content of foods eaten. Table 41-2 presents three sample lunch menus that are interchangeable in terms of carbohydrate, protein, and fat content.

Exchange list information on combination foods, such as pizza, chili, and casseroles, and convenience foods, desserts, snack foods, and fast foods is available from the ADA. Some food manufacturers and restaurants publish exchange lists that describe their products as well. For more nutrition information, contact the ADA (see address at end of the chapter).

The Food Guide Pyramid. The Food Guide Pyramid is another tool used to develop meal plans. It is commonly used for patients with type 2 diabetes who have a difficult time complying with a calorie-controlled diet. The food pyramid consists of six food groups: (1) bread, cereal, rice, and pasta; (2) fruits; (3) vegetables; (4) meat, poultry, fish, dry beans, eggs, and nuts; (5) milk, yogurt, and cheese; and (6) fats, oils, and sweets (see Chap. 5). The pyramid shape was chosen to emphasize that the foods in the largest area, the base of the pyramid (starches, fruits, and vegetables), are lowest in calories and fat and highest in fiber and should make up the basis of the diet. For those with diabetes, as well as for the general population, 50% to 60% of the daily caloric intake should be from these three groups. As one moves up the pyramid, foods higher in fat (particularly saturated fat) are illustrated; these foods should account for a smaller percentage of the daily caloric intake. The very top of the pyramid comprises fats, oils, and sweets, foods that should be used sparingly by people with diabetes to obtain weight and blood glucose control and to reduce the risk for cardiovascular disease. Reliance on the Food Guide Pyramid, however, may result in fluctuations in blood glucose levels because high-carbohydrate foods may be grouped with low-carbohydrate foods. The pyramid is appropriately used only as a first-step teaching tool (Dixon, Cronin, & Krebs-Smith, 2001) for patients learning how to control food portions and how to identify their products as well. For more nutrition information, contact the ADA (see address at end of the chapter).

Glycemic Index. One of the main goals of diet therapy in diabetes is to avoid sharp, rapid increases in blood glucose levels after food is eaten. The term “glycemic index” is used to describe how much a given food raises the blood glucose level compared with an equivalent amount of glucose; however, the effects on blood glucose levels and on long-term patient outcomes have been questioned (ADA, Expert Committee on the Diagnosis and Classification of Diabetes Mellitus, 2003). Although more research is necessary, the following guidelines can be helpful when making dietary recommendations:

- Combining starchy foods with protein- and fat-containing foods tends to slow their absorption and lower the glycemic response.
- In general, eating foods that are raw and whole results in a lower glycemic response than eating chopped, puréed, or cooked foods.
- Eating whole fruit instead of drinking juice decreases the glycemic response because fiber in the fruit slows absorption.
- Adding foods with sugars to the diet may produce a lower glycemic response if these foods are eaten with foods that are more slowly absorbed.

Patients can create their own glycemic index by monitoring their blood glucose level after ingesting a particular food. This can help patients improve blood glucose levels through individualized manipulation of the diet. Many patients who use frequent monitoring of blood glucose levels can use this information to adjust their insulin doses for variations in food intake.

**Other Dietary Concerns**

**ALCOHOL CONSUMPTION**

Patients with diabetes do not need to give up alcoholic beverages entirely, but patients and health care professionals need to be aware of the potential adverse effects of alcohol specific to diabetes. In general, the same precautions regarding the use of alcohol by people without diabetes should be applied to patients with diabetes. Moderation is recommended. The main danger of alcohol consumption by a diabetic patient is hypoglycemia, especially for patients who take insulin. Alcohol may decrease the normal physiologic reactions in the body that produce glucose (gluconeogenesis). Thus, if a diabetic patient takes alcohol on an empty stomach, there is an increased likelihood that hypoglycemia will develop. In addition, excessive alcohol intake may impair the patient’s ability to recognize and treat hypoglycemia and to follow a prescribed meal plan to prevent hypoglycemia. To reduce the risk of hypoglycemia, the patient should be cautioned to eat while drinking alcohol (ADA, Expert Committee on the Diagnosis and Classification of Diabetes Mellitus, 2003).

</table>
For the person with type 2 diabetes treated with the sulfonylurea agent chlorpropamide (Diabinese), a potential side effect of alcohol consumption is a disulfiram (Antabuse) type of reaction, which involves facial flushing, warmth, headache, nausea, vomiting, sweating, or thirst within minutes of consuming alcohol. The intensity of the reaction depends on the amount of alcohol consumed; the reaction seems to be less common with other sulfonylureas.

Alcohol consumption may lead to excessive weight gain (from the high caloric content of alcohol), hyperlipidemia, and elevated glucose levels (especially with mixed drinks and liqueurs).

Patient teaching regarding alcohol intake must emphasize moderation in the amount of alcohol consumed. Lower-calorie or less sweet drinks, such as light beer or dry wine, and food intake along with alcohol consumption are advised. For patients with type 2 diabetes especially, incorporating the calories from alcohol into the overall meal plan is important for weight control.

SWEETENERS
Using sweeteners is acceptable for patients with diabetes, especially if it assists in overall dietary adherence. Moderation in the amount of sweetener used is encouraged to avoid potential adverse effects. There are two main types of sweeteners: nutritive and non-nutritive. The nutritive sweeteners contain calories, and the non-nutritive sweeteners have few or no calories in the amounts normally used.

Nutritive sweeteners include fructose (fruit sugar), sorbitol, and xylitol. They are not calorie-free; they provide calories in amounts similar to those in sucrose (table sugar). They cause less elevation in blood sugar levels than sucrose and are often used in “sugar-free” foods. Sweeteners containing sorbitol may have a laxative effect.

Non-nutritive sweeteners have minimal or no calories. They are used in food products and are also available for table use. They produce minimal or no elevation in blood glucose levels and have been approved by the Food and Drug Administration as safe for people with diabetes. Saccharin contains no calories. Aspartame (NutraSweet) is packaged with dextrose; it contains 4 calories per packet and loses sweetness with heat. Acesulfame-K (Sunnette) is also packaged with dextrose; it contains 1 calorie per packet.Sucralose (Splenda) is a newer non-nutritive, high-intensity sweetener that is about 600 times sweeter than sugar. The Food and Drug Administration has approved it for use in baked goods, nonalcoholic beverages, chewing gum, coffee, confectons, frostings, and frozen dairy products.

MISLEADING FOOD LABELS
Foods labeled “sugarless” or “sugar-free” may still provide calories equal to those of the equivalent sugar-containing products if they are made with nutritive sweeteners. Thus, for weight loss, these products may not always be useful. In addition, patients must not consider them “free” foods to be eaten in unlimited quantity, because they may elevate blood glucose levels.

Foods labeled “dietetic” are not necessarily reduced-calorie foods. They may be lower in sodium or have other special dietary uses. Patients are advised that foods labeled “dietetic” may still contain significant amounts of sugar or fat.

Patients must also be taught to read the labels of “health foods”—especially snacks—because they often contain carbohydrates such as honey, brown sugar, and corn syrup. In addition, these supposedly healthy snacks frequently contain saturated vegetable fats (eg, coconut or palm oil), hydrogenated vegetable fats, or animal fats, which may be contraindicated in patients with elevated blood lipid levels.

EXERCISE
Benefits
Exercise is extremely important in managing diabetes because of its effects on lowering blood glucose and reducing cardiovascular risk factors. Exercise lowers the blood glucose level by increasing the uptake of glucose by body muscles and by improving insulin utilization. It also improves circulation and muscle tone. Resistance (strength) training, such as weight lifting, can increase lean muscle mass, thereby increasing the resting metabolic rate. These effects are useful in diabetes in relation to losing weight, easing stress, and maintaining a feeling of well-being. Exercise also alters blood lipid levels, increasing levels of high-density lipoproteins and decreasing total cholesterol and triglyceride levels. This is especially important to the person with diabetes because of the increased risk of cardiovascular disease (Creviston & Quinn, 2001). General guidelines for exercise in diabetes are presented in Chart 41-5.

Exercise Precautions
Patients who have blood glucose levels exceeding 250 mg/dL (14 mmol/L) and who have ketones in their urine should not begin exercising until the urine tests negative for ketones and the blood glucose level is closer to normal. Exercising with elevated blood glucose levels increases the secretion of glucagon, growth hormone, and catecholamines. The liver then releases more glucose, and the result is an increase in the blood glucose level (ADA, Physical Activity/Exercise and Diabetes Mellitus, 2003).

The physiologic decrease in circulating insulin that normally occurs with exercise cannot occur in patients treated with insulin. Initially, the patient who requires insulin should be taught to eat a 15-g carbohydrate snack (a fruit exchange) or a snack of complex carbohydrate with a protein before engaging in moderate exercise, to prevent unexpected hypoglycemia. The exact amount of food needed varies from person to person and should be determined by blood glucose monitoring. Some patients find that they do not require a pre-exercise snack if they exercise within 1 to 2 hours after a meal. Other patients may require extra food regardless of when they exercise. If extra food is required, it need not be deducted from the regular meal plan.

Another potential problem for patients who take insulin is hypoglycemia that occurs many hours after exercise. To avoid postexercise hypoglycemia, especially after strenuous or prolonged exercise, the patient may need to eat a snack at the end of the exercise session and at bedtime and monitor the blood glucose level.

**Chart 41-5**
General Precautions for Exercise in Diabetics

- Use proper footwear and, if appropriate, other protective equipment.
- Avoid exercise in extreme heat or cold.
- Inspect feet daily after exercise.
- Avoid exercise during periods of poor metabolic control.
more frequently. In addition, it may be necessary to have the patient reduce the dosage of insulin that peaks at the time of exercise. Patients who are capable, knowledgeable, and responsible can learn to adjust their own insulin doses. Others need specific instructions on what to do when they exercise.

Patients participating in extended periods of exercise should test their blood glucose levels before, during, and after the exercise period, and they should snack on carbohydrates as needed to maintain blood glucose levels (ADA, Physical Activity/Exercise and Diabetes Mellitus, 2003). Other participants or observers should be aware that the person exercising has diabetes, and they should know what assistance to give if severe hypoglycemia occurs.

In obese people with type 2 diabetes, exercise in addition to dietary management both improves glucose metabolism and enhances loss of body fat. Exercise coupled with weight loss improves insulin sensitivity and may decrease the need for insulin or oral agents. Eventually, the patient’s glucose tolerance may return to normal. The patient with type 2 diabetes who is not taking insulin or an oral agent may not need extra food before exercise.

Exercise Recommendations

People with diabetes should exercise at the same time (preferably when blood glucose levels are at their peak) and in the same amount each day. Regular daily exercise, rather than sporadic exercise, should be encouraged. Exercise recommendations must be altered as necessary for patients with diabetic complications such as retinopathy, autonomic neuropathy, sensorimotor neuropathy, and cardiovascular disease (ADA, Physical Activity/Exercise and Diabetes Mellitus, 2003). Increased blood pressure associated with exercise may aggravate diabetic retinopathy and increase the risk of a hemorrhage into the vitreous or retina. Patients with ischemic heart disease risk triggering angina or a myocardial infarction, which may be silent. Avoiding trauma to the lower extremities is especially important in the patient with numbness related to neuropathy.

In general, a slow, gradual increase in the exercise period is encouraged. For many patients, walking is a safe and beneficial form of exercise that requires no special equipment (except for proper shoes) and can be performed anywhere. People with diabetes should discuss an exercise program with their physician and undergo a careful medical evaluation with appropriate diagnostic studies before beginning an exercise program (ADA, Physical Activity/Exercise and Diabetes Mellitus, 2003; Creviston & Quinn, 2001; Flood & Constance, 2002).

For patients who are older than 30 years and who have two or more risk factors for heart disease, an exercise stress test is recommended. Risk factors for heart disease include hypertension, obesity, high cholesterol levels, abnormal resting electrocardiogram, sedentary lifestyle, smoking, male gender, and a family history of heart disease.

Gerontologic Considerations

Physical activity that is consistent and realistic is beneficial to the elderly person with diabetes. Physical fitness in the elderly population with diabetes may lead to less chronic vascular disease and an improved quality of life (ADA, Physical Activity/Exercise and Diabetes Mellitus, 2003). Advantages of exercise in this population include a decrease in hyperglycemia, a general sense of well-being, and the use of ingested calories, resulting in weight reduction. Because there is an increased incidence of cardiovascular problems in the elderly, a pattern of gradual, consistent exercise should be planned that does not exceed the patient’s physical capacity. Physical impairment from other chronic diseases must also be considered. In some cases a physical therapy evaluation may be warranted with the goal of determining exercises specific to the patient’s needs and abilities. Tools such as the “Armchair Fitness” video may be helpful. For more information about age-related changes that affect diabetes management see Chart 41-6.

MONITORING GLUCOSE LEVELS AND KETONES

Blood glucose monitoring is a cornerstone of diabetes management, and self-monitoring of blood glucose (SMBG) levels by patients has dramatically altered diabetes care. Frequent SMBG enables people with diabetes to adjust the treatment regimen to obtain optimal blood glucose control. This allows for detection and prevention of hypoglycemia and hyperglycemia and plays a crucial role in normalizing blood glucose levels, which in turn may reduce the risk of long-term diabetic complications.

Various SMBG methods are available. Most involve obtaining a drop of blood from the fingertip, applying the blood to a special reagent strip, and allowing the blood to stay on the strip for the amount of time specified by the manufacturer (usually 5 to 30 seconds). The meter gives a digital readout of the blood glucose value.

</table>
The meters available for SMBG offer different features and benefits. Newer monitors have eliminated the step of blood removal from the strip. The strip is placed in the meter first, before blood is applied to it. Once the blood is placed on the strip, it remains there for the duration of the test. The meter automatically displays the blood glucose level after a short time (less than 1 minute). Some meters are biosensors that use blood obtained from alternate test sites, such as the forearm. They have a special lancing device that is useful for patients who have painful fingertips or pain with finger sticks.

Some meters can be used by patients with visual impairments. They have audio components that assist the patient in performing the test and obtaining the result. In addition, meters are available to check both blood glucose and blood ketone levels by those who are particularly susceptible to development of DKA.

Advantages and Disadvantages of SMBG Systems

The monitoring method used by the patient must match his or her skill level. Factors affecting SMBG performance include visual acuity, fine motor coordination, cognitive ability, comfort with technology, willingness, and cost.

Visual methods are the least expensive and require less equipment. However, they require the ability to distinguish colors and to be exact in timing the procedures. Further, they involve subjective interpretation of results. Monitoring blood glucose using meters is recommended because meters have become much less expensive and less technique-dependent, making the results more accurate. Referral to a social worker may be warranted to assist individuals without the financial means to purchase a meter.

Older meters that required removal of blood from the reagent strip are generally obsolete. These procedures have more steps that must be performed in an exact sequence. The newer meters that do not require removal of blood from the strip generally are easier to use. However, most do not provide a backup method for visually assessing the meter results. Figure 41-3 illustrates a system for glucose monitoring.

A potential hazard of all SMBG methods is that the patient may obtain and report erroneous blood glucose values as a result of using incorrect techniques. Some common sources of error include:

- Improper application of blood (eg, drop too small)
- Improper meter cleaning and maintenance (eg, allowing dust or blood to accumulate on the optic window). This is not an issue in the biosensor type of meter.
- Damage to the reagent strips by heat or humidity; use of outdated strips

The nurse plays an important role in providing initial teaching about SMBG techniques. Equally important is evaluating the techniques of patients who are experienced in self-monitoring. Patients should be discouraged from purchasing SMBG products from stores or catalogs that do not provide direct education. Every 6 to 12 months, patients should conduct a comparison of their meter with a simultaneous laboratory-measured blood glucose level in their physician’s office. The accuracy of the meter and strips should also be assessed with control solutions specific to that meter whenever a new vial of strips is used or whenever the validity of the reading is in doubt.

Candidates for SMBG

For everyone with diabetes, SMBG is useful for managing self-care. It is a key component of treatment for any intensive insulin therapy regimen (including two to four injections per day or insulin pumps) and for diabetes management during pregnancy. It is also recommended for patients with:

- Unstable diabetes
- A tendency for severe ketosis or hypoglycemia
- Hypoglycemia without warning symptoms

For patients not taking insulin, SMBG is helpful for monitoring the effectiveness of exercise, diet, and oral antidiabetic agents. It can also help motivate patients to continue with treatment. For patients with type 2 diabetes, SMBG is recommended during periods of suspected hyperglycemia (eg, illness) or hypoglycemia (eg, unusual increased activity levels) (ADA, Physical Activity/Exercise and Diabetes Mellitus, 2003).

Frequency of SMBG

For most patients who require insulin, SMBG is recommended two to four times daily (usually before meals and at bedtime). For patients who take insulin before each meal, SMBG is required at least three times daily before meals to determine each dose (ADA, Tests of Glycemia in Diabetes, 2002). Patients not receiving insulin may be instructed to assess their blood glucose levels at least two or three times per week, including a 2-hour postprandial test. For all patients, testing is recommended whenever hypoglycemia or hyperglycemia is suspected. The patient should increase the frequency of SMBG with changes in medications, activity, or diet and with stress or illness.

Responding to SMBG Results

Patients are instructed to keep a record or logbook of blood glucose levels so that they can detect patterns. Testing is done at the peak action time of the medication to evaluate the need for dosage adjustments. To evaluate basal insulin and determine bolus insulin doses, testing is performed before meals. To titrate bolus insulin doses, regular or lispro, testing is done 2 hours after meals. Patients with type 2 diabetes are encouraged to test before and 2 hours after the largest meal of the day. Patients who take insulin at bedtime or who are on an insulin infusion pump must also test at 3 a.m. once a week to document that the blood glucose level is not decreasing during the night. If a patient is unwilling or cannot afford to test frequently, then once or twice a day may be sufficient if the patient varies the time of day to test (eg, before breakfast one day, before lunch the next day).
A tendency to discontinue SMBG is more likely to occur when patients do not receive instruction about using the results to alter their treatment regimen. Instructions vary according to the patient’s understanding and the physician’s philosophy of diabetes management. At the very least, patients should be given parameters for calling the physician. Patients using intensive insulin therapy regimens may be instructed in the use of algorithms (rules or decision trees) for changing the insulin doses based on patterns of values greater or less than the target range and the amount of carbohydrate to be consumed. Baseline patterns should be established by SMBG for 1 to 2 weeks.

**Glycosylated Hemoglobin**

Glycosylated hemoglobin (referred to as HgbA1C or A1C) is a blood test that reflects average blood glucose levels over a period of approximately 2 to 3 months (ADA, Tests of Glycemia in Diabetes, 2003). When blood glucose levels are elevated, glucose molecules attach to hemoglobin in the red blood cell. The longer the amount of glucose in the blood remains above normal, the more glucose binds to the red blood cell and the higher the glycosylated hemoglobin level. This complex (the hemoglobin attached to the glucose) is permanent and lasts for the life of the red blood cell, approximately 120 days. If near-normal blood glucose levels are maintained, with only occasional increases in blood glucose, the overall value will not be greatly elevated. However, if the blood glucose values are consistently high, then the test result will also be elevated. If patients report mostly normal SMBG results but the glycosylated hemoglobin is high, there may be errors in the methods used for glucose monitoring, errors in recording results, or frequent elevations in blood glucose levels. Values within the normal range indicate consistently near-normal blood glucose levels, a goal made easier by SMBG.

**Urine Testing for Glucose**

Before SMBG methods were available, urine glucose testing was the only way to monitor diabetes on a daily basis. Today its use is limited to patients who cannot or will not perform SMBG. The advantages of urine glucose testing are that it is less expensive than SMBG and it is not invasive. The general procedure involves applying urine to a reagent strip or tablet and matching colors on the strip with a color chart at the end of a specified period. Baseline patterns should be established by SMBG for 1 to 2 weeks.

**Testing for Ketones**

Ketones (or ketone bodies) in the urine signal that control of type 1 diabetes is deteriorating, and the risk of DKA is high. When there is almost no effective insulin available, the body starts to break down stored fat for energy. Ketone bodies are byproducts of this fat breakdown, and they accumulate in the blood and urine. Urine testing is the most common method used for self-testing of ketone bodies by patients. A meter that enables testing of blood for ketones is available but not widely used.

Most commonly, patients use a urine dipstick (Ketostix or Chemstrip uK) to detect ketonuria. The reagent pad on the strip turns purplish when ketones are present. (One of the ketone bodies is called acetone, and this term is frequently used interchangeably with the term “ketones.”) Other strips are available for measuring both urine glucose and ketones (Keto-Diastix or Chemstrip uGK). Large amounts of ketones may depress the color response of the glucose test area.

Urine ketone testing should be performed whenever patients with type 1 diabetes have glucosuria or persistently elevated blood glucose levels (more than 240 mg/dL or 13.2 mmol/L for two testing periods in a row) and during illness, in pregnancy with pre-existing diabetes, and in gestational diabetes (ADA, Tests of Glycemia in Diabetes, 2003).

**PHARMACOLOGIC THERAPY**

As stated earlier, insulin is secreted by the beta cells of the islets of Langerhans and works to lower the blood glucose level after meals by facilitating the uptake and utilization of glucose by muscle, fat, and liver cells. In the absence of adequate insulin, pharmacologic therapy is essential.

**Insulin Therapy and Insulin Preparations**

Because the body loses the ability to produce insulin in type 1 diabetes, exogenous insulin must be administered for life. In type 2 diabetes, insulin may be necessary on a long-term basis to control glucose levels if diet and oral agents fail. In addition, some patients in whom type 2 diabetes is usually controlled by diet alone or by diet and an oral agent may require insulin temporarily during illness, infection, pregnancy, surgery, or some other stressful event. In many cases, insulin injections are administered two or more times daily to control the blood glucose level. Because the insulin dose required by the individual patient is determined by the level of glucose in the blood, accurate monitoring of blood glucose levels is essential; thus, SMBG has become a cornerstone of insulin therapy. A number of insulin preparations are available. They vary according to three main characteristics: time course of action, species (source), and manufacturer.

**TIME COURSE OF ACTION**

Insulins may be grouped into several categories based on the onset, peak, and duration of action (Table 41-3). Human insulin preparations have a shorter duration of action than insulin from animal sources because the presence of animal proteins triggers an immune response that results in the binding of animal insulin, which slows its availability.

Rapid-acting insulins such as insulin lispro (Humalog) and insulin aspart (Novolog) are blood glucose-lowering agents that start to appear in the urine is raised; thus, false-negative readings may occur at dangerously elevated glucose levels.
produce a more rapid effect that is of shorter duration than regular insulin. These insulins have an onset of 5 to 15 minutes, a peak action of 1 hour after injection, and a duration of 2 to 4 hours. Because of their rapid onset, patients should be instructed to eat no more than 5 to 15 minutes after injection. Because of the short duration of action of these insulin analogs, patients with type 1 diabetes and some patients with type 2 or gestational diabetes also require a long-acting insulin to maintain glucose control. Basal insulin is necessary to maintain blood glucose levels irrespective of meals. A constant level of insulin is required at all times. Intermediate-acting insulins function as basal insulins but may have to be split into two injections to achieve 24-hour coverage.

Short-acting insulins, called regular insulin (marked R on the bottle), have an onset of 30 minutes to 1 hour; peak, 2 to 3 hours; and duration, 4 to 6 hours. Regular insulin is a clear solution and is usually administered 20 to 30 minutes before a meal, either alone or in combination with a longer-acting insulin. Humulin R, Iletin Regular, and Novolin R are examples of regular insulin.

Intermediate-acting insulins, called NPH insulin (neutral protamine Hagedorn) or Lente insulin, have an onset of 3 to 4 hours; peak, 4 to 12 hours; and duration, 16 to 20 hours. Intermediate-acting insulins, which are similar in their time course of action, appear white and cloudy. If NPH or Lente insulin is taken alone, it is not crucial that it be taken 30 minutes before the meal. It is important, however, for the patient to eat some food around the time of the onset and peak of these insulins. Humulin N, Iletin NPH, and Novolin N are examples of NPH insulins; Humulin L, Iletin L, and Novolin L are examples of Lente insulins.

Long-acting insulins, called Ultralente (“UL”) or Ultratard, have a peakless action that is absorbed slowly over 24 hours and can be given once a day. Because the insulin is in a suspension with a pH of 4, it cannot be mixed with other insulins because this would cause precipitation. It is given once a day at bedtime.

</table>

**NURSING ALERT** When administering insulin, it is very important to read the label carefully and to be sure that the correct type of insulin is administered. It is also important to avoid mistaking Lantus insulin for Lente insulin and vice versa.

In the future, “inhaled insulin” may be approved for use. This type of insulin is in the form of a very fine powder, which is inhaled through a device similar to that used to administer asthma medications. The patient’s program would consist of a “basal” rate of insulin such as glargine supplemented by an inhaled dose before each meal.

The nurse may find that different sources list differing numbers of hours for the onset, peak, and duration of action of the main types of insulin, and patients’ responses may vary (ie, larger doses prolong onset, duration, and peak). The nurse should focus on which meals—and snacks—are being “covered” by which insulin doses. In general, the rapid- and short-acting insulins are expected to cover the rise in glucose levels after meals, immediately after the injection; the intermediate-acting insulins are expected to cover subsequent meals; and the long-acting insulins provide a relatively constant level of insulin and act as a basal insulin.

**SPECIES (SOURCE)** In the past, all insulins were obtained from beef (cow) and pork (pig) pancreases. “Human insulins” are now widely available. They are produced by recombinant DNA technology and have largely replaced insulin from animal sources (ADA, Insulin Administration, 2003).

**MANUFACTURER** The two manufacturers of insulin in the United States are Eli-Lilly and Novo Nordisk. The insulins made by the different
companies are usually interchangeable, provided the concentration (eg, U-100), species (eg, human), and type (eg, NPH) of insulin are the same. Human insulins made by different companies have different brand names. Therefore, a patient taking 20 units human NPH insulin may be using either Humulin N or Novolin N.

Insulin Regimens

Insulin regimens vary from one to four injections per day. Usually there is a combination of a short-acting insulin and a longer-acting insulin. The normally functioning pancreas continuously secretes small amounts of insulin during the day and night. In addition, whenever blood glucose rises after ingestion of food, there is a rapid burst of insulin secretion in proportion to the glucose-raising effect of the food. The goal of all but the simplest, one-injection insulin regimens is to mimic this normal pattern of insulin secretion in response to food intake and activity patterns. Table 41-4 describes several insulin regimens and the advantages and disadvantages of each.

Patients can learn to use SMBG results and carbohydrate counting to vary the insulin doses. This allows patients more flexibility in the timing and content of meals and exercise periods. However, complex insulin regimens require a strong level of commitment, intensive education, and close follow-up by the health care team. In addition, patients aiming for normal blood glucose levels run the risk of more hypoglycemic reactions.

The type of regimen used by any particular patient varies. For example, patient knowledge, willingness, goals, health status, and finances all may affect decisions regarding insulin treatment. In addition, the physician’s philosophy about blood glucose control and the availability of equipment and support staff may influence decisions regarding insulin therapy. There are two general approaches to insulin therapy: conventional and intensive.

CONVENTIONAL REGIMEN

One approach is to simplify the insulin regimen as much as possible, with the aim of avoiding the acute complications of diabetes (hypoglycemia and symptomatic hyperglycemia). With this type of simplified regimen (eg, one or more injections of a mixture of short- and intermediate-acting insulins per day), patients may frequently have blood glucose levels well above normal. The exception is the patient who never varies meal patterns and activity levels. This approach would be appropriate for the terminally ill, the frail elderly with limited self-care abilities, or any patient who is completely unwilling or unable to engage in the self-management activities that are part of a more complex insulin regimen.

INTENSIVE REGIMEN

The second approach is to use a more complex insulin regimen to achieve as much control over blood glucose levels as is safe and practical. The results of the landmark DCCT study (1993) and the UKPDS study (1998) have demonstrated that maintaining blood glucose levels as close to normal as possible prevents or slows the progression of long-term diabetic complications. Another reason for using a more complex insulin regimen is to allow patients more flexibility to change their insulin doses from day to day in accordance with changes in their eating and activity patterns, with stress and illness, and as needed for variations in the prevailing glucose level.

Although the DCCT found that intensive treatment (three or four injections of insulin per day) reduced the risk of complications, not all people with diabetes are candidates for very tight control of blood glucose. The risk for severe hypoglycemia was increased threefold in patients receiving intensive treatment in the DCCT (ADA, Implications of the Diabetes Control and Complications Trial, 2003). Those who may not be candidates include patients with:

- Nervous system disorders rendering them unaware of hypoglycemic episodes (eg, those with autonomic neuropathy)
- Recurring severe hypoglycemia
- Irreversible diabetic complications, such as blindness or end-stage renal disease
- Cerebrovascular and/or cardiovascular disease
- Ineffective self-care skills

An exception is the patient who has received a kidney transplant because of nephropathy and chronic renal failure; this patient should be on an intensive regimen to preserve function of the new kidney.

The patient needs to be involved in the decision regarding which insulin regimen to use. Patients need to compare the potential benefits of different regimens with the potential costs (eg, time involved, number of injections or finger sticks for glucose testing, amount of record-keeping). There are no set guidelines as to which insulin regimen should be used for which patients. It must not be assumed that an elderly patient or a patient with visual impairment should automatically be given a simplified regimen. Likewise, it must not be assumed that all people will want to be involved in a complex treatment regimen. Nurses play an important role in educating patients about the different approaches to insulin therapy. Nurses should refer patients to diabetes specialists or diabetes education centers, when available, for further training and education in the various insulin treatment regimens.

Complications of Insulin Therapy

LOCAL ALLERGIC REACTIONS

A local allergic reaction (redness, swelling, tenderness, and induration or a 2- to 4-cm wheel) may appear at the injection site 1 to 2 hours after the insulin administration. These reactions, which usually occur during the beginning stages of therapy and disappear with continued use of insulin, are becoming rare because of the increased use of human insulins. The physician may prescribe an antihistamine to be taken 1 hour before the injection if such a local reaction occurs.

SYSTEMIC ALLERGIC REACTIONS

Systemic allergic reactions to insulin are rare. When they do occur, there is an immediate local skin reaction that gradually spreads into generalized urticaria (hives). The treatment is desensitization, with small doses of insulin administered in gradually increasing amounts using a desensitization kit. These rare reactions are occasionally associated with generalized edema or anaphylaxis.

INSULIN LIPODYSTROPHY

Lipodystrophy refers to a localized reaction, in the form of either lipoatrophy or lipo hypertrophy, occurring at the site of insulin injections. Lipoatrophy is loss of subcutaneous fat and appears as slight dimpling or more serious pitting of subcutaneous fat. The use of human insulin has almost eliminated this disfiguring complication.

Lipo hypertrophy, the development of fibrofatty masses at the injection site, is caused by the repeated use of an injection site. If insulin is injected into scarred areas, absorption may be delayed.

![Diagram showing regular insulin injections]

Uses ONLY regular insulin infused at continuous, low rate called *basal rate* (commonly 0.5–1.5 units/hour) and premeal *bolus doses* activated by pump wearer

Most closely mimics normal pancreas Decreases unpredictable peaks of intermediate- and long-acting insulins Increases meal and exercise flexibility Requires intensive training and frequent follow-up Potential for mechanical problems Requires multiple blood glucose tests on a daily basis Potential increase in expenses (depending on insurance coverage)

BR, breakfast; LU, lunch; DI, dinner; SN, snack; REG, regular; ↑ indicates insulin injections.
This is one reason that rotation of injection sites is so important. The patient should avoid injecting insulin into these areas until the hypertrophy disappears.

**INSULIN RESISTANCE**

Most patients at one time or another have some degree of insulin resistance. This may occur for various reasons, the most common being obesity, which can be overcome by weight loss. Clinical insulin resistance has been defined as a daily insulin requirement of 200 units or more. In most diabetic patients taking insulin, immune antibodies develop and bind the insulin, thereby decreasing the insulin available for use. All animal insulins, as well as human insulins to a lesser degree, cause antibody production in humans.

Very few resistant patients develop high levels of antibodies. Many of these patients have a history of insulin therapy interrupted for several months or more. Treatment consists of administering a more concentrated insulin preparation, such as U500, which is available by special order. Occasionally, prednisone is needed to block the production of antibodies. This may be followed by a gradual reduction in insulin requirement. Therefore, patients need to monitor themselves for hypoglycemia.

**MORNING HYPERGLYCEMIA**

An elevated blood glucose level upon arising in the morning may be caused by an insufficient level of insulin due to several causes: the dawn phenomenon, the Somogyi effect, or insulin waning. The dawn phenomenon is characterized by a relatively normal blood glucose level until approximately 3 a.m., when blood glucose levels begin to rise. The phenomenon is thought to result from nocturnal surges in growth hormone secretion that create a greater need for insulin in the early morning hours in patients with type 1 diabetes. It must be distinguished from insulin waning (the progressive increase in blood glucose from bedtime to morning) or the Somogyi effect (nocturnal hyperglycemia followed by rebound hyperglycemia). Insulin waning is frequently seen if the evening NPH dose is administered before dinner and is prevented by moving the evening dose of NPH insulin to bedtime.

It may be difficult to tell from the patient’s history which of these causes is responsible for morning hyperglycemia. To determine the cause, the patient must be awakened once or twice during the night to test blood glucose levels. Testing the blood glucose level at bedtime, at 3 a.m., and on awakening provides information that can be used in making adjustments in insulin to avoid morning hyperglycemia caused by the dawn phenomenon.

Table 41-5 summarizes the differences among insulin waning, the dawn phenomenon, and the Somogyi effect.

**Alternative Methods of Insulin Delivery**

### INSULIN PENS

These devices use small (150- to 300-unit) prefilled insulin cartridges that are loaded into a penlike holder. A disposable needle is attached to the device for insulin injection. Insulin is delivered by dialing in a dose or pushing a button for every 1- or 2-unit increment administered. People using these devices still need to insert the needle for each injection; however, they do not need to carry insulin bottles or to draw up insulin before each injection. These devices are most useful for patients who need to inject only one type of insulin at a time (eg, premeal regular insulin three times a day and bedtime NPH insulin) or who can use the premixed insulins. These pens are convenient for those who administer insulin before dinner if eating out or traveling. They are also useful for patients with impaired manual dexterity, vision, or cognitive function that makes the use of traditional syringes difficult.

**JET INJECTORS**

As an alternative to needle injections, jet injection devices deliver insulin through the skin under pressure in an extremely fine stream. These devices are more expensive than other alternative devices mentioned above and require thorough training and supervision when first used. In addition, patients should be cautioned that absorption rates, peak insulin activity, and insulin levels may be different when changing to a jet injector. (Insulin administered by jet injector is usually absorbed faster.) Bruising has occurred in some patients with use of the jet injector.

**INSULIN PUMPS**

Continuous subcutaneous insulin infusion involves the use of small, externally worn devices that closely mimic the functioning of the normal pancreas (ADA, Continuous Subcutaneous Insulin Infusion, 2003). Insulin pumps contain a 3-mL syringe attached to a long (24- to 42-in), thin, narrow-lumen tube with a needle or Teflon catheter attached to the end (Figs. 41-4 and 41-5). The patient inserts the needle or catheter into the subcutaneous tissue (usually on the abdomen) and secures it with tape or a transparent dressing. The needle or catheter is changed at least every 3 days. The pump is then worn either on a belt or in a pocket. Some women keep the pump tucked into the front or side of the bra or wear it on a garter belt on the thigh.

The rapid-acting lispro insulin is used in the insulin pump and is delivered at a basal rate and as a bolus with meals. A continuous basal rate of insulin is typically 0.5 to 2.0 units/hour, depending on the patient’s needs. A bolus dose of insulin is delivered before each meal when the patient activates the pump (by pushing buttons). The patient determines the amount of insulin to infuse based on blood glucose levels and anticipated food intake and activity level. Advantages of insulin pumps include increased flexibility in lifestyle (in terms of timing and amount of
meals, exercise, and travel) and, for many patients, improved blood glucose control.

A disadvantage of insulin pumps is that unexpected disruptions in the flow of insulin from the pump may occur if the tubing or needle becomes occluded, if the supply of insulin runs out, or if the battery is depleted, increasing the risk of DKA. Effective teaching and a knowledgeable patient can minimize this risk. Another disadvantage is the potential for infection at needle insertion sites. Hypoglycemia may occur with insulin pump therapy; however, this is usually related to the lowered blood glucose levels many patients achieve rather than to a specific problem with the pump itself. The tight diabetic control associated with using an insulin pump may increase the incidence of hypoglycemia unawareness because of the very gradual decline in serum glucose level from levels greater than 70 mg/dL (3.9 mmol/L) to those less than 60 mg/dL (3.3 mmol/L).

Some patients find that wearing the pump for 24 hours each day is an inconvenience. However, the pump can easily be disconnected, per patient preference, for limited periods (eg, for showering, exercise, or sexual activity).

Insulin pump candidates must be willing to assess blood glucose levels multiple times daily while on pump therapy. In addition, they must be psychologically stable and open about having diabetes, because the insulin pump is often a visible sign to others and a constant reminder to the patient that he or she has diabetes. Most important, patients using insulin pumps must have extensive education in the use of the insulin pump and in self-management of blood glucose and insulin doses. They must work closely with a team of health care professionals who are experienced in insulin pump therapy—specifically, a diabetologist/endocrinologist, a dietitian, and a certified diabetes educator.

Many insurance policies cover the cost of pump therapy; if it is not covered, the extra expense of the pump and associated supplies may be a deterrent for some patients. Medicare now covers insulin pump therapy for the patient with type 1 diabetes.

**IMPLANTABLE AND INHALANT INSULIN DELIVERY**

Research into mechanical delivery of insulin has involved implantable insulin pumps that can be externally programmed according to blood glucose test results. Clinical trials with these devices are continuing. In addition, there is research into the development of implantable devices that both measure the blood glucose level and deliver insulin as needed. Methods of administering insulin by the oral route (oral spray or capsule), skin patch, and inhalation are undergoing intensive study.

**TRANSPLANTATION OF PANCREATIC CELLS**

Transplantation of the whole pancreas or a segment of the pancreas is being performed on a limited population (mostly diabetic patients receiving kidney transplantations simultaneously). One main issue regarding pancreatic transplantation is weighing the risks of antirejection medications against the advantages of pancreas transplantation. Another approach under investigation is the implantation of insulin-producing pancreatic islet cells (ADA, Pancreas Transplantation for Patients With Type 1 Diabetes, 2003). This latter approach involves a less extensive surgical procedure and a potentially lower incidence of immunogenic problems. However, thus far, independence from exogenous insulin has been limited to 2 years after transplantation of islet cells. A recent study of patients with islet cell transplants using less toxic antirejection drugs has shown promise (Shapiro et al., 2000).
Oral Antidiabetic Agents

Oral antidiabetic agents may be effective for patients who have type 2 diabetes that cannot be treated by diet and exercise alone; however, they cannot be used during pregnancy. In the United States, oral antidiabetic agents include the sulfonylureas, biguanides, alpha glucosidase inhibitors, thiazolidinediones, and meglitinides (Table 41-6). Sulfonylureas and meglitinides are considered insulin secretagogues because their action increases the secretion of insulin by the pancreatic beta cells.

SULFONYLUREAS

The sulfonylureas exert their primary action by directly stimulating the pancreas to secrete insulin. Therefore, a functioning pancreas is necessary for these agents to be effective, and they cannot be used in patients with type 1 diabetes. These agents improve insulin action at the cellular level and may also directly decrease glucose production by the liver. The sulfonylureas can be divided into first- and second-generation categories (see Table 41-6).

The most common side effects of these medications are GI symptoms and dermatologic reactions. Hypoglycemia may occur when an excessive dose of a sulfonylurea is used or when the patient omits or delays meals, reduces food intake, or increases activity. Because of the prolonged hypoglycemic effects of these agents (especially chlorpropamide), some patients need to be hospitalized for treatment of oral agent-induced hypoglycemia. Another side effect of chlorpropamide is a disulfiram (Antabuse) type of reaction when alcohol is ingested (see section on alcohol consumption for more information). Some medications may directly interact with sulfonylureas, potentiating their hypoglycemic effects (eg, sulfonamides, chloramphenicol, clofibrate, phenylbutazone, and bishydroxycoumarin). In addition, certain medications may independently affect blood glucose levels, thereby indirectly interfering with these agents. Medications that may increase glucose levels include potassium-losing diuretics, corticosteroids, estrogen compounds, and diphenylhydantoin (Dilantin). Medications that may cause hypoglycemia include salicylates, propranolol, monoamine oxidase inhibitors, and pentamidine.

Second-generation sulfonylureas have the advantage of a shorter half-life and excretion by both the kidney and the liver. This makes these medications safer to use in the elderly, in whom accumulation of the medication can cause recurring hypoglycemia.

BIGUANIDES

The biguanides are other kinds of oral antidiabetic agents. Metformin (Glucophage) produces its antidiabetic effects by facilitating insulin's action on peripheral receptor sites. Therefore, it can be used only in the presence of insulin. Biguanides have no effect on pancreatic beta cells. Biguanides used with a sulfonylurea may enhance the glucose-lowering effect more than either medication used alone. Lactic acidosis is a potential and serious complication of biguanide therapy; the patient must be monitored closely when therapy is initiated or when dosage changes. Med-

D = divided dose; S = single dose
ications that may interact with biguanides include anticoagulants, corticosteroids, diuretics, and oral contraceptives. Metformin is contraindicated in patients with renal impairment (serum creatinine level more than 1.4) or those at risk for renal dysfunction (eg, those with acute myocardial infarction). Renal function studies should be performed periodically to ensure that function is not impaired. Metformin should not be administered for 2 days before any diagnostic testing that may require use of a contrast agent. These situations increase the risk for lactic acidosis.

An extended-release form and a combination form (Glucovan) combines metformin with a sulfonylurea, such as glyburide. The combination provides two mechanisms of action and improved patient compliance. Hypoglycemia is a risk.

ALPHA GLUCOSIDASE INHIBITORS
Acarbose (Precose) and miglitol (Glyset) are oral alpha glucosidase inhibitors used in type 2 diabetes management. They work by delaying the absorption of glucose in the intestinal system, resulting in a lower postprandial blood glucose level. As a consequence of plasma glucose reduction, hemoglobin A1c levels drop. In contrast to the sulfonylureas, acarbose and miglitol do not enhance insulin secretion. They can be used alone with dietary treatment as monotherapy or in combination with sulfonylureas, thiazolidinediones, or meglitinides. When these medications are used in combination with sulfonylureas or meglitinides, hypoglycemia may occur. The patient must be advised that if hypoglycemia occurs, sucrose absorption will be blocked and treatment for hypoglycemia should be in the form of glucose, such as glucose tablets. The advantage of oral alpha glucosidase inhibitors is that they are not systemically absorbed and are safe to use. Their side effects are diarrhea and flatulence. These effects may be minimized by starting at a very low dose and increasing the dose gradually. Because acarbose and miglitol affect food absorption, they must be taken immediately before a meal, making therapeutic adherence a potential problem.

THIAZOLIDINEDIONES
Rosiglitizone (Avandia) and pioglitazone (Actos) are oral diabetes medications categorized as thiazolidinediones. They are indicated for patients with type 2 diabetes who take insulin injections and whose blood glucose control is inadequate (hemoglobin A1c level greater than 8.5%). They have also been approved as first-line agents to treat type 2 diabetes, in combination with diet. Thiazolidinediones enhance insulin action at the receptor site without increasing insulin secretion from the beta cells of the pancreas. These medications may affect liver function; therefore, liver function studies must be performed at baseline and at frequent intervals (monthly for the first 12 months of treatment, and quarterly thereafter). Women should be informed that thiazolidinediones can cause resumption of ovulation in perimenopausal anovulatory women, making pregnancy a possibility.

MEGLITINIDES
Repaglinide (Prandin), an oral glucose-lowering agent of the class of oral agents called meglitinides, lowers the blood glucose level by stimulating insulin release from the pancreatic beta cells. Its effectiveness depends on the presence of functioning beta cells. Therefore, repaglinide is contraindicated in patients with type 1 diabetes. Repaglinide has a fast action and a short duration. It should be taken before each meal to stimulate the release of insulin in response to that meal. It is also indicated for use in combination with metformin in patients whose hyperglycemia cannot be controlled by exercise, diet, and either metformin or repaglinide alone. The principal side effect of repaglinide is hypoglycemia; however, this side effect is less severe and frequent than for a sulfonylurea because repaglinide has a short half-life (approximately 1 hour). Patients must be taught the signs and symptoms of hypoglycemia and should understand that the medication should not be taken unless the patient eats a meal. Repaglinide is supplied in 0.5-, 1-, and 2-mg tablets.

Naglitinide (Starlix), another meglitinide, has a very rapid onset and short duration. It should be taken with meals and not taken if the meal is skipped. Hypoglycemia risk is low if taken correctly.

General Considerations for Oral Agents
Patients need to understand that oral agents are prescribed as an addition to (not as a substitute for) other treatment modalities, such as diet and exercise. Use of oral antidiabetic medications may need to be halted temporarily and insulin prescribed if hyperglycemia develops that is attributable to infection, trauma, or surgery.

In time, oral antidiabetic agents may no longer be effective in controlling the patient’s diabetes. In such cases, the patient is treated with insulin. Approximately half of all patients who initially use oral antidiabetic agents eventually require insulin. This is referred to as a secondary failure. Primary failure occurs when the blood glucose level remains high a month after initial medication use.

Because the mechanisms of action vary (Fig. 41-6), the effect may be enhanced using multidose, multiple medications (Inzucchi et al., 1998). Use of multiple medications with different mechanisms of action is very common today (Quinn, 2001b). Using a combination of oral agents with insulin has been proposed as a treatment for some patients with type 2 diabetes. However, the effectiveness of this approach has not yet been demonstrated.

Nursing Management
Nursing management of the patient with diabetes can involve treatment of a wide variety of physiologic disorders, depending on the patient’s health status and whether the patient is newly diagnosed or seeks care for an unrelated health problem. Nursing management of the newly diagnosed patient and the patient with diabetes as a secondary diagnosis is presented in subsequent sections of this chapter. Because all diabetic patients must master the concepts and skills necessary for long-term management of diabetes and its potential complications, a solid educational foundation is necessary for competent self-care and is an ongoing focus of nursing care.

EDUCATION
Diabetes mellitus is a chronic illness requiring a lifetime of special self-management behaviors. Because diet, physical activity, and physical and emotional stress affect diabetic control, patients must learn to balance a multitude of factors. They must learn daily self-care skills to prevent acute fluctuations in blood glucose, and they must also incorporate into their lifestyle many preventive behaviors for avoidance of long-term diabetic complications. Diabetic patients must become knowledgeable about nutrition, medication effects and side effects, exercise, disease progression, prevention strategies, blood glucose monitoring techniques, and
medication adjustment. In addition, they must learn the skills associated with monitoring and managing diabetes and must incorporate many new activities into their daily routines. An appreciation for the knowledge and skills that diabetic patients must acquire can help the nurse in providing effective patient education and counseling (Beebe & O’Donnell, 2001).

**DEVELOPING A DIABETIC TEACHING PLAN**

Changes in the health care delivery system as a whole have had a major impact on diabetes education and training. Patients with new-onset type 1 diabetes have much shorter hospital stays or may be managed completely on an outpatient basis; patients with new-onset type 2 diabetes are rarely hospitalized for initial care. There has been a proliferation of outpatient diabetes education and training programs, with increasing support of third-party reimbursement. For some patients, however, exposure to diabetes education during hospitalization may be the only opportunity for learning self-management skills and preventing complications.

Many hospitals employ nurses who specialize in diabetes education and management and who are certified by the National Certification Board of Diabetes Educators as Certified Diabetes Educators. However, because of the large number of diabetic patients who are admitted to every unit of a hospital for reasons other than diabetes or its complications, the staff nurse plays a vital role in identifying diabetic patients, assessing self-care skills, providing basic education, reinforcing the teaching provided by the specialist, and referring patients for follow-up care after discharge. Diabetes patient education programs that have been peer-reviewed by the ADA as meeting National Standards for Diabetes Education can seek reimbursement for education.

**Organizing Information**

There are various strategies for organizing and prioritizing the vast amount of information that must be taught to diabetic patients. In addition, many hospitals and outpatient diabetes centers have devised written guidelines, care plans, and documentation forms (often based on guidelines from the ADA) that may be used to document and evaluate teaching. A general approach is to organize information and skills into two main types: basic, initial, or “survival” skills and information, and in-depth (advanced) or continuing education.

**TEACHING SURVIVAL SKILLS**

This information must be taught to any patient with newly diagnosed type 1 or type 2 diabetes and any patient receiving insulin for the first time. This basic information is literally what the patient must know to survive—that is, to avoid severe hypoglycemic or acute hyperglycemic complications after discharge. An outline of survival information includes:

1. Simple pathophysiology
   a. Basic definition of diabetes (having a high blood glucose level)
   b. Normal blood glucose ranges and target blood glucose levels
   c. Effect of insulin and exercise (decrease glucose)
   d. Effect of food and stress, including illness and infections (increase glucose)
   e. Basic treatment approaches
2. Treatment modalities
   a. Administration of insulin and oral antidiabetes medications
   b. Diet information (food groups, timing of meals)
   c. Monitoring of blood glucose and ketones
3. Recognition, treatment, and prevention of acute complications
   a. Hypoglycemia
   b. Hyperglycemia
4. Pragmatic information
   a. Where to buy and store insulin, syringes, and glucose monitoring supplies
   b. When and how to reach the physician

For patients with newly diagnosed type 2 diabetes, emphasis is initially placed on diet. Patients starting to take oral sulfonylureas or meglitinides need to know about detecting, preventing,
and treating hypoglycemia. If diabetes has gone undetected for many years, the patient may already be experiencing some chronic diabetic complications. Thus, for some patients with newly diagnosed type 2 diabetes, the basic diabetes teaching must include information on preventive skills, such as foot care and eye care—for example, planning yearly or more frequent complete (dilated eye) examinations by the ophthalmologist and understanding that retinopathy is largely asymptomatic until the advanced stages.

Patients also need to realize that once they master the basic skills and information, further diabetes education must be pursued. Acquiring in-depth and advanced diabetes knowledge occurs throughout the patient’s lifetime, both formally through programs of continuing education and informally through experience and sharing of information with other people with diabetes.

PLANNING IN-DEPTH AND CONTINUING EDUCATION
This involves teaching more detailed information related to survival skills (eg, learning to vary diet and insulin and preparing for travel) as well as learning preventive measures for avoiding long-term diabetic complications. Preventive measures include:

- Foot care
- Eye care
- General hygiene (eg, skin care, oral hygiene)
- Risk factor management (eg, control of blood pressure and blood lipid levels, and normalizing blood glucose levels)

More advanced continuing education may include alternative methods for insulin delivery, such as the insulin pump, and algorithms or rules for evaluating and adjusting insulin doses. For example, patients can be taught to increase or decrease insulin doses based on a several-day pattern of blood glucose levels. The degree of advanced diabetes education to be provided depends on the patient’s interest and ability. However, learning preventive measures (especially foot care and eye care) is mandatory for reducing the occurrence of amputations and blindness in diabetic patients.

Assessing Readiness to Learn
Before initiating diabetes education, the nurse assesses the patient’s (and family’s) readiness to learn (Beebe & O’Donnell, 2001). When patients are first diagnosed with diabetes (or first told of their need for insulin), they often go through various stages of the grieving process. These stages may include shock and denial, anger, depression, negotiation, and acceptance. The amount of time it takes for patients and family members to work through the grieving process varies from patient to patient. They may experience helplessness, guilt, altered body image, loss of self-esteem, and concern about the future. The nurse must assess the patient’s coping strategies and reassure patients and families that feelings of depression and shock are normal.

Asking the patient and family about their major concerns or fears is an important way to learn about any misinformation that may be contributing to anxiety. Some common misconceptions regarding diabetes and its treatment are listed in Table 41-7. Simple, direct information should be provided to dispel misconceptions. More information can be provided once the patient masters survival skills.

After dispelling misconceptions or answering questions that concern the patient the most, the nurse focuses attention on concrete survival skills. Because of the immediate need for multiple new skills, teaching is initiated as soon as possible after diagnosis. Nurses whose patients are in the hospital rarely have the luxury of waiting until the patient feels ready to learn; short hospital stays necessitate initiation of survival skill education as early as possible. This gives the patient the opportunity to practice skills with supervision by the nurse before discharge. Follow-up by home health nurses is often necessary for reinforcement of survival skills.

A major goal of patient teaching is an educated consumer, a patient who is informed about the wide variations in the prices of medications and supplies and about the importance of comparing prices.

Determining Teaching Methods
Maintaining flexibility in teaching approaches is important. Teaching skills and information in a logical sequence is not always the most helpful for patients. For example, many patients fear the injection. Before they learn how to draw up, purchase, store, and mix insulins, they should be taught to insert the needle and inject insulin (or practice with saline solution). Numerous demonstrations by the nurse or practice injections before the patient (or family) gives the first injection may actually increase the patient’s anxiety and fear of self-injection. Once patients have actually performed the injection, most are more prepared to hear and to comprehend other information. (If they then want to practice further using a pillow or an orange, that would be appropriate.) Thus, having patients self-inject first or having patients perform a fingerstick for glucose monitoring first may enhance learning to draw up the insulin or to operate the glucose meter. Ample opportunity should be provided for the patient and family to practice skills under supervision (including self-injection, self-testing, meal selection, verbalization of symptoms, and treatment of hypoglycemia). Once skills have been mastered, participation in ongoing support groups may assist patients in incorporating new habits and maintaining adherence to the treatment regimen.

Various tools can be used to complement teaching. Many of the companies that manufacture products for diabetes self-care also provide booklets and videotapes to assist in patient teaching. It is important to use a variety of written handouts that match the patient’s learning needs (including different languages, low-literacy information, large print). Patients can continue learning about diabetes care by participating in activities sponsored by local hospitals and diabetes organizations. In addition, magazines with information on all aspects of diabetes management are available for people with diabetes.

IMPLEMENTING THE PLAN
Teaching Experienced Diabetic Patients
The nurse should continue to assess the skills of patients who have had diabetes for many years, because it is estimated that up to 50% of patients may make errors in self-care. Assessment of these patients must include direct observation of skills, not just their self-report of self-care behaviors. In addition, these patients must be fully aware of preventive measures related to foot care, eye care, and risk factor management. If patients are experiencing long-term diabetic complications for the first time, they may go through the grieving process again. Some of these patients may have a renewed interest in diabetes self-care in the hope of delaying further complications. Other patients may be overwhelmed by feelings of guilt and depression. The patient is encouraged to discuss feelings and fears related to complications; the nurse meanwhile provides appropriate information regarding diabetic complications.
Teaching Patients to Self-Administer Insulin

Insulin injections are administered into the subcutaneous tissue with the use of special insulin syringes. A variety of syringes and injection-aid devices are available. Chart 41-7 provides important information to include and evaluate when teaching patients about insulin. Basic information includes explanation of the equipment, insulins, syringes, and mixing insulin.

STORING INSULIN

Cloudy insulins should be thoroughly mixed by gently inverting the vial or rolling it between the hands before drawing the solution into a syringe or a pen.

Whether insulin is the short- or long-acting preparation, the vials not in use should be refrigerated and extremes of temperature should be avoided; insulin should not be allowed to freeze and should not be kept in direct sunlight or in a hot car. The insulin vial in use should be kept at room temperature to reduce local irritation at the injection site, which may occur when cold insulin is injected. If a vial of insulin will be used up in 1 month, it may be kept at room temperature. Patients should be instructed to always have a spare vial of the type or types of insulin they use (ADA, Insulin Administration, 2003). Spare vials should be refrigerated.

Insulin bottles should also be inspected for flocculation, which is a frosted, whitish coating inside the bottle of intermediate- or long-acting insulins. This occurs most commonly with human insulins that are not refrigerated. If a frosted, adherent coating is present, some of the insulin is bound and should not be used.

SELECTING SYRINGES

Syringes must be matched with the insulin concentration (eg, U-100). Currently, three sizes of U-100 insulin syringes are available:

1. With one hand, stabilize the skin by spreading it or pinching up a large area.
2. Pick up syringe with the other hand and hold it as you would a pencil. Insert needle straight into the skin.*
3. To inject the insulin, push the plunger all the way in.
4. Pull needle straight out of skin. Press cotton ball over injection site for several seconds.
5. Use disposable syringe only once and discard into hard plastic container (with a tight-fitting top) such as an empty bleach or detergent container.† Follow state regulations for disposal of syringes and needles.

*Some patients may be taught to insert the needle at a 45-degree angle.
†Although some studies suggest that reusing disposable syringes may be safe, it is recommended that this be done only in the absence of poor personal hygiene, an acute concurrent illness, open wounds on the hands, or decreased resistance to infection.
• 1-mL (cc) syringes that hold 100 units
• 0.5-mL syringes that hold 50 units
• 0.3-mL syringes that hold 30 units

The concentration of insulin used in the United States is U-100; that is, there are 100 units per milliliter (or cubic centimeter). Syringe size varies. Small syringes allow patients who require small amounts of insulin to measure and draw up the amount of insulin accurately. Patients who require large amounts of insulin would use larger syringes. Although there is a U-500 (500 units/mL) concentration of insulin available by special order for patients who have severe insulin resistance and require massive doses of insulin, it is rarely used. (Individuals who travel outside of the United States should be aware that insulin is available in 40-U concentration to avoid dosing errors.)

Most insulin syringes have a disposable 27- to 29-gauge needle that is approximately 0.5 inch long. The smaller syringes are marked in 1-unit increments and may be easier to use for patients with visual deficits or patients taking very small doses of insulin. The 1-mL syringes are marked in 2-unit increments. A small disposable insulin needle (29- to 30-gauge, 8 mm long) is available for very thin patients and children.

**PREPARING THE INJECTION: MIXING INSULINS**

When rapid- or short-acting insulins are to be given simultaneously with longer-acting insulins, they are usually mixed together in the same syringe; the longer-acting insulins must be mixed thoroughly before use. There is some question as to whether the two insulins are stable if the mixture is kept in the syringe for more than 5 to 15 minutes. This may depend on the ratio of the insulins as well as the time between mixing and injecting. When regular insulin is mixed with long-acting insulin, there is a binding reaction that slows the action of the regular insulin. This may also occur to a greater degree when mixing regular insulin with one of the Lente insulins. Patients are advised to consult their health care provider for advice on this matter. The most important issue is that patients be consistent in how they prepare their insulin injections from day to day.

While there are varying opinions regarding which type of insulin (short- or longer-acting) should be drawn up into the syringe first when they are going to be mixed, the ADA recommends that the regular insulin be drawn up first. The most important issues are, again, that patients be consistent so as not to draw up the wrong dose accidentally or the wrong type of insulin, and that patients not inject one type of insulin into the bottle containing a different type of insulin (ADA, Insulin Administration, 2003).

For patients who have difficulty mixing insulins, two options are available: they may use a premixed insulin, or they may have prefilled syringes prepared. Premixed insulins are available in several different ratios of NPH insulin to regular insulin. The ratio of 70/30 (70% NPH and 30% regular insulin in one bottle) is the most common and is available as Novolin 70/30 (Novo Nordisk) and Humulin 70/30 (Lilly). Other ratios available include 80/20, 60/40, and 50/50. The ratio of 75% NPL and 25% insulin lispro is also available (ADA, Insulin Administration, 2002). NPL is used only to mix with Humalog; its action is the same as NPH. The appropriate initial dosage of premixed insulin must be calculated so that the ratio of NPH to regular insulin most closely approximates the separate doses needed.

For patients who can inject insulin but who have difficulty drawing up a single or mixed dose, syringes can be prefilled with the help of home care nurses or family and friends. A 3-week supply of insulin syringes may be prepared and kept in the refrigerator. The prefilled syringes should be stored with the needle in an upright position to avoid clogging of the needle (ADA, Insulin Administration, 2003).

**WITHDRAWING INSULIN**

Most (if not all) of the printed materials available on insulin dose preparation instruct patients to inject air into the bottle of insulin equivalent to the number of units of insulin to be withdrawn. The rationale for this is to prevent the formation of a vacuum inside the bottle, which would make it difficult to withdraw the proper amount of insulin. Some nurses who specialize in diabetes report that some patients (who have been taking insulin for many years) have stopped injecting air before withdrawing the insulin. These patients found that the extra step was not necessary for accurately drawing up the insulin dose. Most patients find it easier to withdraw the insulin by eliminating the step and report no difficulty in preparing the proper insulin dose.

Eliminating this step (or alternating it by, for instance, injecting a syringe full of air into the vial once per week) facilitates the teaching process for some patients learning to draw up insulin for the first time. Some patients become confused with the sequence of steps involved in injecting air into two separate bottles in two different amounts before drawing up a mixed dose. For many individuals, including elderly ones, simplifying the procedure for preparing insulin injections may help them maintain independence in daily living.

As with other variations in insulin injection technique, the most important factors are that the patient maintain consistency in the procedure and that the nurse be flexible when teaching new patients or assessing the skills of experienced patients.

**SELECTING AND ROTATING THE INJECTION SITE**

The four main areas for injection are the abdomen, arms (posterior surface), thighs (anterior surface), and hips (Fig. 41-7). Insulin is absorbed faster in some areas of the body than others. The speed of absorption is greatest in the abdomen and decreases progressively in the arm, thigh, and hip.

Systematic rotation of injection sites within an anatomic area is recommended to prevent localized changes in fatty tissue (lipodystrophy). In addition, to promote consistency in insulin absorption, patients should be encouraged to use all available injection sites within one area rather than randomly rotating sites from area to area (ADA, Insulin Administration, 2002). For example, some patients almost exclusively use the abdominal area, administering each injection 0.5 to 1 inch away from the previous injection. Another approach to rotation is always to use the same area at the same time of day. For example, patients may inject morning doses into the abdomen and evening doses into the arms or legs.

A few general principles apply to all rotation patterns. First, patients should try not to use the same site more than once in 2 to 3 weeks. In addition, if the patient is planning to exercise, insulin should not be injected into the limb that will be exercised, because it will be absorbed faster, and this may result in hypoglycemia.

In the past, patients were taught to rotate injections from one area to the next (eg, injecting once in the right arm, then once in the right abdomen, then once in the right thigh). Patients who still use this system must be taught to avoid repeated injections into the same site within an area. However, as previously stated, it is preferable for the patient to use the same anatomic
Area at the same time of day consistently; this reduces day-to-day variation in blood glucose levels because of different absorption rates.

PREPARING THE SKIN
Use of alcohol to cleanse the skin is not recommended, but patients who have learned this technique often continue to use it. They should be cautioned to allow the skin to dry after cleansing with alcohol. If the skin is not allowed to dry before the injection, the alcohol may be carried into the tissues, resulting in a localized reddened area.

INSERTING THE NEEDLE
There are varying approaches to inserting the needle for insulin injections. The correct technique is based on the need for the insulin to be injected into the subcutaneous tissue. Injection that is too deep (e.g., intramuscular) or too shallow may affect the rate of absorption of the insulin. Aspiration (inserting the needle and then pulling back on the plunger to assess for blood being drawn into the syringe) is generally not recommended with self-injection of insulin. Many patients who have been using insulin for an extended period have eliminated this step from their insulin injection routine with no apparent adverse effects.

PROMOTING HOME AND COMMUNITY-BASED CARE
Teaching Patients Self-Care. Adherence to the therapeutic plan is the most important goal of self-care the patient must master. Patients who are having difficulty adhering to the diabetes treatment plan must be approached with care and understanding. Using scare tactics (such as threats of blindness or amputation if the patient does not adhere to the treatment plan) or making the patient feel guilty is not productive and may interfere with establishing a trusting relationship with the patient. Judgmental actions, such as asking the patient if he or she has “cheated” on the diet, only promote feelings of guilt and low self-esteem.

If problems exist with glucose control or with the development of preventable complications, it is important to distinguish among nonadherence, knowledge deficit, and self-care deficit. It should not be assumed that problems with diabetes management are related to nonadherence. The patient may simply have forgotten or never learned certain information. The problem may be correctable simply through providing complete information and ensuring that the patient comprehends the information. Chart 41-8 details how to evaluate the effectiveness of self-injection of insulin.

If knowledge deficit is not the problem, certain physical or emotional factors may be impairing the patient’s ability to perform self-care skills. For example, decreased visual acuity may impair the patient’s ability to administer insulin accurately, measure the blood glucose level, or inspect the skin and feet. In addition, decreased joint mobility (especially in the elderly) impairs the ability to inspect the bottom of the feet. Emotional factors such as denial of the diagnosis or depression may impair the patient’s ability to carry out multiple daily self-care measures. In other circumstances, family, personal, or work problems may be of higher priority to the patient. The patient facing competing demands for time and attention may benefit from assistance in establishing priorities. It is also important to assess the patient for infection or emotional stress that may lead to elevated blood glucose levels despite adherence to the treatment regimen.

The following approaches by the nurse are helpful for promoting self-care management skills:

- Address any underlying factors (e.g., knowledge deficit, self-care deficit, illness) that may affect diabetic control.
- Simplify the treatment regimen if it is too difficult for the patient to follow.
- Adjust the treatment regimen to meet patient requests (e.g., adjust diet or insulin schedule to allow increased flexibility in meal content or timing).
- Establish a specific plan or contract with the patient with simple, measurable goals.
- Provide positive reinforcement of self-care behaviors performed instead of focusing on behaviors that were neglected (e.g., positively reinforce blood glucose tests that were performed instead of focusing on the number of missed tests).
- Help the patient to identify personal motivating factors rather than focusing on wanting to please the doctor or nurse.
- Encourage the patient to pursue life goals and interests; discourage an undue focus on diabetes.

Continuing Care. As discussed, continuing care of the patient with diabetes is critical in managing and preventing complications. The degree to which the client interacts with health care providers to obtain ongoing care depends on many factors. Age, socioeconomic level, existing complications, type of diabetes, and comorbid conditions all may dictate the frequency of follow-up visits. Many patients with diabetes may be seen by home health nurses for diabetic education, wound care, insulin preparation, or assistance with glucose monitoring. Even patients who achieve
excellent glucose control and have no complications can expect to see their primary health care provider at least twice a year for ongoing evaluation.

In addition to follow-up care with health professionals, participation in support groups is encouraged for those who have had diabetes for many years as well as those who are newly diagnosed. Such participation may assist the patient and family in coping with changes in lifestyle that occur with the onset of diabetes and with its complications. Those who participate in support groups often have an opportunity to share valuable information and experience and to learn from others. Support groups provide an opportunity for discussion of strategies to deal with diabetes and its management and to clarify and verify information with the nurse or other health care professionals. Participation in support groups may help patients and their families to become more knowledgeable about diabetes and its management and may promote adherence to the management plan. Another very important role of the nurse is to remind the patient about participation in other health promotion activities and recommended health screening.

**Acute Complications of Diabetes**

There are three major acute complications of diabetes related to short-term imbalances in blood glucose levels: hypoglycemia, DKA, and HHNS, which is also called hyperglycemic hyperosmolar nonketotic coma or hyperglycemic hyperosmolar syndrome.

**HYPOGLYCEMIA (INSULIN REACTIONS)**

Hypoglycemia (abnormally low blood glucose level) occurs when the blood glucose falls to less than 50 to 60 mg/dL (2.7 to 3.3 mmol/L). It can be caused by too much insulin or oral hypoglycemic agents, too little food, or excessive physical activity. Hypoglycemia may occur at any time of the day or night. It often occurs before meals, especially if meals are delayed or snacks are omitted. For example, midmorning hypoglycemia may occur when the morning regular insulin is peaking, whereas hypoglycemia that occurs in the late afternoon coincides with the peak of the morning NPH or Lente insulin. Middle-of-the-night hypoglycemia may occur because of peaking evening or predinner
Clinical Manifestations

The clinical manifestations of hypoglycemia may be grouped into two categories: adrenergic symptoms and central nervous system (CNS) symptoms. In mild hypoglycemia, as the blood glucose level falls, the sympathetic nervous system is stimulated, resulting in a surge of epinephrine and norepinephrine. This causes symptoms such as sweating, tremor, tachycardia, palpitation, nervousness, and hunger.

In moderate hypoglycemia, the fall in blood glucose level deprives the brain cells of needed fuel for functioning. Signs of impaired function of the CNS may include inability to concentrate, headache, lightheadedness, confusion, memory lapses, numbness of the lips and tongue, slurred speech, impaired coordination, emotional changes, irrational or combative behavior, double vision, and drowsiness. Any combination of these symptoms (in addition to adrenergic symptoms) may occur with moderate hypoglycemia.

In severe hypoglycemia, CNS function is so impaired that the patient needs the assistance of another person for treatment of hypoglycemia. Symptoms may include disoriented behavior, seizures, difficulty arousing from sleep, or loss of consciousness.

Assessment and Diagnostic Findings

Hypoglycemic symptoms can occur suddenly and unexpectedly. The combination of symptoms varies considerably from person to person. To some degree, this may be related to the actual level to which the blood glucose drops or to the rate at which it is dropping. For example, patients who usually have a blood glucose level in the hyperglycemic range (eg, in the 200s or greater) may feel hypoglycemic (adrenergic) symptoms when their blood glucose quickly drops to 120 mg/dL (6.6 mmol/L) or less. Conversely, patients who frequently have a glucose level in the low range of normal may be asymptomatic when the blood glucose slowly falls to less than 50 mg/dL (2.7 mmol/L).

Another factor contributing to altered hypoglycemic symptoms is a decreased hormonal (adrenergic) response to hypoglycemia. This occurs in some patients who have had diabetes for many years. It may be related to one of the chronic diabetic complications, autonomic neuropathy (see the section in this chapter on hypoglycemic unawareness). As the blood glucose level falls, the normal surge in adrenalin does not occur. The patient does not feel the usual adrenergic symptoms, such as sweating and shakiness. The hypoglycemia may not be detected until moderate or severe CNS impairment occurs. These patients must perform SMBG on a frequent regular basis, especially before driving or engaging in other potentially dangerous activities.

Gerontologic Considerations

In the elderly diabetic patient, hypoglycemia is a particular concern for many reasons:

- Elderly people frequently live alone and may not recognize the symptoms of hypoglycemia.
- With decreasing renal function, it takes longer for oral hypoglycemic agents to be excreted by the kidneys.
- Skipping meals may occur because of decreased appetite or financial limitations.
- Decreased visual acuity may lead to errors in insulin administration.

Management

Immediate treatment must be given when hypoglycemia occurs. The usual recommendation is for 15 g of a fast-acting concentrated source of carbohydrate such as the following, given orally:

- Three or four commercially prepared glucose tablets
- 4 to 6 oz of fruit juice or regular soda
- 6 to 10 Life Savers or other hard candies
- 2 to 3 teaspoons of sugar or honey

It is not necessary to add sugar to juice, even if it is labeled as unsweetened juice: the fruit sugar in juice contains enough carbohydrate to raise the blood glucose level. Adding table sugar to juice may cause a sharp increase in the blood glucose level, and the patient may experience hyperglycemia for hours after treatment.

The blood glucose level should be retested in 15 minutes and retreated if it is less than 70 to 75 mg/dL (3.8 to 4 mmol/L). If the symptoms persist more than 10 to 15 minutes after initial treatment, the treatment is repeated even if blood glucose testing is not possible. Once the symptoms resolve, a snack containing protein and starch (eg, milk or cheese and crackers) is recommended unless the patient plans to eat a regular meal or snack within 30 to 60 minutes.

TEACHING PATIENTS

It is important for patients with diabetes, especially those receiving insulin, to learn that they must carry some form of simple sugar with them at all times (ADA, Insulin Administration, 2002). There are many different commercially prepared glucose tablets and gels that patients may find convenient to carry. If the patient has a hypoglycemic reaction and does not have any of the recommended emergency foods available, any available food (preferably a carbohydrate food) should be eaten.

Patients are advised to refrain from eating high-calorie, high-fat dessert foods (eg, cookies, cakes, doughnuts, ice cream) to treat hypoglycemia. The high fat content of these foods may slow the absorption of the glucose, and the hypoglycemic symptoms may not resolve as quickly as they would with the intake of carbohydrates. The patient may subsequently eat more of the foods when symptoms do not resolve rapidly. This in turn may cause very high blood glucose levels for several hours after the reaction and may also contribute to weight gain.

Patients who feel unduly restricted by their meal plan may view hypoglycemic episodes as a time to reward themselves with desserts. It may be more prudent to teach these patients to incorporate occasional desserts into the meal plan. This may make it easier for them to limit their treatment of hypoglycemic episodes to simple (low-calorie) carbohydrates such as juice or glucose tablets.

INITIATING EMERGENCY MEASURES

For patients who are unconscious and cannot swallow, an injection of glucagon 1 mg can be administered either subcutaneously or intramuscularly. Glucagon is a hormone produced by the alpha cells of the pancreas that stimulates the liver to release glucose (through the breakdown of glycogen, the stored glucose). Injectable glucagon is packaged as a powder in 1-mg vials and must be mixed with a diluent before being injected. After injection of glucagon, it may take up to 20 minutes for the patient to regain consciousness. A concentrated source of carbohydrate followed by a snack should be given to the patient on awakening to pre-
vent recurrence of hypoglycemia (because the duration of the action of 1 mg of glucagon is brief [its onset is 8 to 10 minutes and its action lasts 12 to 27 minutes]) and to replenish liver stores of glucose. Some patients experience nausea after the administration of glucagon; if this occurs, the patient should be turned to the side to prevent aspiration. The patient should be instructed to notify the physician after severe hypoglycemia has occurred.

Glucagon is sold by prescription only and should be part of the emergency supplies kept available by patients with diabetes who require insulin. Family members, neighbors, or coworkers should be instructed in the use of glucagon. This is especially true for patients who receive little or no warning of hypoglycemic episodes.

In the hospital or emergency department, patients who are unconscious or cannot swallow may be treated with 25 to 50 mL 50% dextrose in water (D50W) administered intravenously. The effect is usually seen within minutes. Patients may complain of a headache and of pain at the injection site. Assuring patency of the intravenous (IV) line used for injection of 50% dextrose is essential because hypertonic solutions such as 50% dextrose are very irritating to the vein.

PROMOTING HOME AND COMMUNITY-BASED CARE

Teaching Patients Self-Care. Hypoglycemia is prevented by a consistent pattern of eating, administering insulin, and exercising. Between-meal and bedtime snacks may be needed to counteract the maximum insulin effect. In general, the patient should cover the time of peak activity of insulin by eating a snack and by taking additional food when physical activity is increased. Routine blood glucose tests are performed so that changing insulin requirements may be anticipated and the dosage adjusted. Because unexpected hypoglycemia may occur, all patients treated with insulin should wear an identification bracelet or tag stating that they have diabetes.

Patients and family members must be instructed about the symptoms of hypoglycemia. Family members in particular must be made aware that any subtle (but unusual) change in behavior may be an indication of hypoglycemia. They should be taught to encourage and even insist that the person with diabetes assess blood glucose levels if hypoglycemia is suspected. Some patients (when hypoglycemic) become very resistant to testing or eating and become angry at family members trying to treat the hypoglycemia. Family members must be taught to persevere and to understand that the hypoglycemia can cause irrational behavior.

Some patients with autonomic neuropathy or those taking beta blockers such as propranolol to treat hypertension or cardiac dysrhythmias may not experience the typical symptoms of hypoglycemia. It is very important for these patients to perform blood glucose tests on a frequent and regular basis. Patients who have type 2 diabetes and who take oral sulfonylurea agents may also develop hypoglycemia (especially those taking chlorpropamide, a long-lasting oral hypoglycemic agent).

DIABETIC KETOACIDOSIS

DKA is caused by an absence or markedly inadequate amount of insulin. This deficit in available insulin results in disorders in the metabolism of carbohydrate, protein, and fat. The three main clinical features of DKA are:

- Hyperglycemia
- Dehydration and electrolyte loss
- Acidosis

Pathophysiology

Without insulin, the amount of glucose entering the cells is reduced and the liver increases glucose production. Both factors lead to hyperglycemia. In an attempt to rid the body of the excess glucose, the kidneys excrete the glucose along with water and electrolytes (eg, sodium and potassium). This osmotic diuresis, which is characterized by excessive urination (polyuria), leads to dehydration and marked electrolyte loss. Patients with severe DKA may lose up to 6.5 liters of water and up to 400 to 500 mEq each of sodium, potassium, and chloride over a 24-hour period.

Another effect of insulin deficiency or deficit is the breakdown of fat (lipolysis) into free fatty acids and glycerol. The free fatty acids are converted into ketone bodies by the liver. In DKA there is excessive production of ketone bodies because of the lack of insulin that would normally prevent this from occurring. Ketone bodies are acids; their accumulation in the circulation leads to metabolic acidosis.

Three main causes of DKA are decreased or missed dose of insulin, illness or infection, and undiagnosed and untreated diabetes (DKA may be the initial manifestation of diabetes). An insulin deficit may result from an insufficient dosage of insulin prescribed or from insufficient insulin being administered by the patient. Errors in insulin dosage may be made by patients who are ill and who assume that if they are eating less or if they are vomiting, they must decrease their insulin doses. (Because illness, especially infections, may cause increased blood glucose levels, patients do not need to decrease their insulin doses to compensate for decreased food intake when ill and may even need to increase the insulin dose.)

Other potential causes of decreased insulin include patient error in drawing up or injecting insulin (especially in patients with visual impairments), intentional skipping of insulin doses (especially in adolescents with diabetes who are having difficulty coping with diabetes or other aspects of their lives), or equipment problems (eg, occlusion of insulin pump tubing).

Illness and infections are associated with insulin resistance. In response to physical (and emotional) stressors, there is an increase in the level of “stress” hormones—glucagon, epinephrine, norepinephrine, cortisol, and growth hormone. These hormones promote glucose production by the liver and interfere with glucose utilization by muscle and fat tissue, counteracting the effect of insulin. If insulin levels are not increased during times of illness and infection, hyperglycemia may progress to DKA (Quinn, 2001c).

Clinical Manifestations

The signs and symptoms of DKA are listed in Figure 41-8. The hyperglycemia of DKA leads to polyuria and polydipsia (increased thirst). In addition, patients may experience blurred vision, weakness, and headache. Patients with marked intravascular volume depletion may have orthostatic hypotension (drop in systolic blood pressure of 20 mm Hg or more on standing). Volume depletion may also lead to frank hypotension with a weak, rapid pulse.

The ketosis and acidosis of DKA lead to GI symptoms such as anorexia, nausea, vomiting, and abdominal pain. The abdominal pain and physical findings on examination can be so severe that they resemble an acute abdominal disorder that requires surgery. Patients may have acetone breath (a fruity odor), which occurs with elevated ketone levels. In addition, hyperventilation (with
very deep, but not labored, respirations) may occur. These Kussmaul respirations represent the body’s attempt to decrease the acidosis, counteracting the effect of the ketone buildup. In addition, mental status changes in DKA vary widely from patient to patient. Patients may be alert, lethargic, or comatose, most likely depending on the plasma osmolarity (concentration of osmotically active particles).

**Assessment and Diagnostic Findings**

Blood glucose levels may vary from 300 to 800 mg/dL (16.6 to 44.4 mmol/L). Some patients have lower glucose values, and others have values of 1,000 mg/dL (55.5 mmol/L) or more (usually depending on the degree of dehydration). The severity of DKA is not necessarily related to the blood glucose level. Some patients may have severe acidosis with modestly elevated blood glucose levels, whereas others may have no evidence of DKA despite blood glucose levels of 400 to 500 mg/dL (22.2 to 27.7 mmol/L) (Quinn, 2001c).

Evidence of ketoacidosis is reflected in low serum bicarbonate (0 to 15 mEq/L) and low pH (6.8 to 7.3) values. A low PCO₂ level (10 to 30 mm Hg) reflects respiratory compensation (Kussmaul respirations) for the metabolic acidosis. Accumulation of ketone bodies (which precipitates the acidosis) is reflected in blood and urine ketone measurements.

Sodium and potassium levels may be low, normal, or high, depending on the amount of water loss (dehydration). Despite the plasma concentration, there has been a marked total body depletion of these (and other) electrolytes. Ultimately, these electrolytes will need to be replaced.

Elevated levels of creatinine, blood urea nitrogen (BUN), hemoglobin, and hematocrit may also be seen with dehydration. After rehydration, continued elevation in the serum creatinine and BUN levels will be present in the patient with underlying renal insufficiency.

**Prevention**

For prevention of DKA related to illness, patients must be taught “sick day” rules for managing their diabetes when ill (Chart 41-9). The most important issue to teach patients is not to eliminate insulin doses when nausea and vomiting occur. Rather, they should take their usual insulin dose (or previously prescribed special “sick day” doses) and then attempt to consume frequent small portions of carbohydrates (including foods usually avoided, such as juices, regular sodas, and gelatin). Drinking fluids every hour is important to prevent dehydration. Blood glucose and urine ketones must be assessed every 3 to 4 hours.

If the patient cannot take fluids without vomiting, or if elevated glucose or ketone levels persist, the physician must be contacted. Patients are taught to have available foods for use on sick days. In addition, a supply of urine test strips (for ketone testing) and blood glucose test strips should be available. Patients must know how to contact their physician 24 hours a day.

Diabetes self-management skills (including insulin administration and blood glucose testing) should be assessed to ensure that an error in insulin administration or blood glucose testing did not occur. Psychological counseling is recommended for patients and family members if an intentional alteration in insulin dosing was the cause of the DKA.
Chart 41-9 • PATIENT EDUCATION
Guidelines to Follow During Periods of Illness (“Sick Day Rules”)

- Take insulin or oral antidiabetic agents as usual.
- Test blood glucose and test urine ketones every 3 to 4 hours.
- Report elevated glucose levels (greater than 300 mg/dL [16.6 mmol/L] or as otherwise specified) or urine ketones to the physician.
- Insulin-requiring patients may need supplemental doses of regular insulin every 3 to 4 hours.
- If usual meal plan cannot be followed, substitute soft foods (eg, ½ cup regular gelatin, 1 cup cream soup, ½ cup custard, 3 squares graham crackers) six to eight times per day.
- If vomiting, diarrhea, or fever persists, take liquids (eg, ½ cup regular cola or orange juice, ½ cup broth, 1 cup Gatorade) every ½ to 1 hour to prevent dehydration and to provide calories.
- Report nausea, vomiting, and diarrhea to the physician, because extreme fluid loss may be dangerous.
- For patients with type 1 diabetes, inability to retain oral fluids, may warrant hospitalization to avoid diabetic ketoacidosis and possibly coma.

Medical Management
In addition to treating hyperglycemia, management of DKA is aimed at correcting dehydration, electrolyte loss, and acidosis (Quinn, 2001c).

REHYDRATION
In dehydrated patients, rehydration is important for maintaining tissue perfusion. In addition, fluid replacement enhances the excretion of excessive glucose by the kidneys. Patients may need up to 6 to 10 liters of IV fluid to replace fluid losses caused by polyuria, hyperventilation, diarrhea, and vomiting.

Initially, 0.9% sodium chloride (normal saline) solution is administered at a rapid rate, usually 0.5 to 1 L per hour for 2 to 3 hours. Half-strength normal saline (0.45%) solution (also known as hypotonic saline solution) may be used for patients with hypertension or hypotension or those at risk for heart failure. After the first few hours, half-normal saline solution is the fluid of choice for continued rehydration, if the blood pressure is stable and the sodium level is not low. Moderate to high rates of infusion (200 to 500 mL per hour) may continue for several more hours. When the blood glucose level reaches 300 mg/dL (16.6 mmol/L) or less, the IV fluid may be changed to dextrose 5% in water (D5W) to prevent a precipitous decline in the blood glucose level (ADA, Hyperglycemic Crisis in Patients with Diabetes Mellitus, 2003).

Monitoring fluid volume status involves frequent measurements of vital signs (including monitoring for orthostatic changes in blood pressure and heart rate), lung assessment, and monitoring intake and output. Initial urine output will lag behind IV fluid intake as dehydration is corrected. Plasma expanders may be necessary to correct severe hypotension that does not respond to IV fluid treatment. Monitoring for signs of fluid overload is especially important for older patients, those with renal impairment, or those at risk for heart failure.

RESTORING ELECTROLYTES
The major electrolyte of concern during treatment of DKA is potassium. Although the initial plasma concentration of potassium may be low, normal, or even high, there is a major loss of potassium from body stores and an intracellular to extracellular shift of potassium. Further, the serum level of potassium drops during the course of treatment of DKA as potassium re-enters the cells; therefore, it must be monitored frequently. Some of the factors related to treating DKA that reduce the serum potassium concentration include:

- Rehydration, which leads to increased plasma volume and subsequent decreases in the concentration of serum potassium. Rehydration also leads to increased urinary excretion of potassium.
- Insulin administration, which enhances the movement of potassium from the extracellular fluid into the cells.

Cautious but timely potassium replacement is vital to avoid dysrhythmias that may occur with hypokalemia. Up to 40 mEq per hour may be needed for several hours. Because extracellular potassium levels drop during DKA treatment, potassium must be infused even if the plasma potassium level is normal.

Frequent (every 2 to 4 hours initially) electrocardiograms and laboratory measurements of potassium are necessary during the first 8 hours of treatment. Potassium replacement is withheld only if hyperkalemia is present or if the patient is not urinating.

REVERSING ACIDOSIS
Ketone bodies (acids) accumulate as a result of fat breakdown. The acidosis that occurs in DKA is reversed with insulin, which inhibits fat breakdown, thereby stopping acid buildup. Insulin is usually infused intravenously at a slow, continuous rate (eg, 5 units per hour). Hourly blood glucose values must be measured. IV fluid solutions with higher concentrations of glucose, such as normal saline (NS) solution (eg, D5NS or D50.4–5NS), are administered when blood glucose levels reach 250 to 300 mg/dL (13.8 to 16.6 mmol/L) to avoid too rapid a drop in the blood glucose level.

Various IV mixtures of regular insulin may be used. The nurse must convert hourly rates of insulin infusion (frequently prescribed as “units per hour”) to IV drip rates. For example, if 100 units of regular insulin are mixed in 500 mL 0.9% NS, then 1 unit of insulin equals 5 mL. Thus, an initial insulin infusion rate of 5 units per hour would equal 25 mL per hour. The insulin is often infused separately from the rehydration solutions to allow frequent changes in the rate and content of rehydration solutions.

NURSING ALERT When mixing the insulin drip, it is important to flush the insulin solution through the entire IV infusion set and to discard the first 50 mL of fluid. Insulin molecules adhere to the inner surface of IV infusion sets; thus, the initial fluid may contain a decreased concentration of insulin.

Insulin must be infused continuously until subcutaneous administration of insulin resumes. Any interruption in adminis-
Nursing Management

Nursing care of the patient with DKA focuses on monitoring fluid and electrolyte status as well as blood glucose levels; administering fluids, insulin, and other medications; and preventing other complications such as fluid overload. Urine output is monitored to ensure adequate renal function before potassium is administered to prevent hyperkalemia. The electrocardiogram is monitored for dysrhythmias indicating abnormal potassium levels. Vital signs, arterial blood gases, and other clinical findings are recorded on a flow sheet. The nurse documents the patient’s laboratory values and the frequent changes in fluids and medications that are prescribed and monitors the patient’s responses. As DKA resolves and the potassium replacement rate is decreased, the nurse makes sure that:

- There are no signs of hyperkalemia on the electrocardiogram (tall, peaked [or tented] T waves).
- The laboratory values of potassium are normal or low.
- The patient is urinating (ie, no renal shutdown).

As the patient recovers, the nurse reassesses the factors that may have led to DKA and teaches the patient and family about strategies to prevent its recurrence (Quinn, 2001c). If indicated, the nurse initiates a referral for home care to ensure the patient’s continued recovery.

**HYPERGLYCEMIC HYPEROSMOLAR NONKETOTIC SYNDROME**

HHNS is a serious condition in which hyperosmolarity and hyperglycemia predominate, with alterations of the sensorium (sense of awareness). At the same time, ketosis is minimal or absent. The basic biochemical defect is lack of effective insulin (ie, insulin resistance). The patient’s persistent hyperglycemia causes osmotic diuresis, resulting in losses of water and electrolytes. To maintain osmotic equilibrium, water shifts from the intracellular fluid space to the extracellular fluid space. With glucosuria and dehydration, hypernatremia and increased osmolarity occur. Table 41-8 compares DKA and HHNS.

This condition occurs most often in older people (ages 50 to 70) with no known history of diabetes or with mild type 2 diabetes. HHNS can be traced to a precipitating event such as an acute illness (eg, pneumonia or stroke), medications that exacerbate hyperglycemia (thiazides), or treatments, such as dialysis. The history includes days to weeks of polyuria with adequate fluid intake. What distinguishes HHNS from DKA is that keto- sis and acidosis do not occur in HHNS partly because of differences in insulin levels. In DKA no insulin is present, and this promotes the breakdown of stored glucose, protein, and fat, which leads to the production of ketone bodies and ketoacidosis. In HHNS the insulin level is too low to prevent hyperglycemia (and subsequent osmotic diuresis), but it is high enough to prevent fat breakdown. Patients with HHNS do not have the ketosis-related GI symptoms that lead them to seek medical attention. Instead, they may tolerate polyuria and polydipsia until neurologic changes or an underlying illness (or family members or others) prompts them to seek treatment. Because of possible delays in therapy, hyperglycemia, dehydration, and hyperosmolarity may be more severe in HHNS (Quinn, 2001c).

| Table 41-8 • Comparison of Diabetic Ketoacidosis (DKA) and Hyperglycemic Hyperosmolar Nonketotic Syndrome (HHNS) |
|---------------------------------|---------------------------------|---------------------------------|
| **CHARACTERISTICS**            | **DKA**                         | **HHNS**                        |
| Patients most commonly affected| Can occur in type 1 or type 2 diabetes; more common in type 1 diabetes | Can occur in type 1 or type 2 patients; more common in type 2 diabetes, especially elderly patients with type 2 diabetes |
| Precipitating event            | Omission of insulin; physiologic stress (infection, surgery, CVA, MI) | Physiologic stress (infection, surgery, CVA, MI) |
| Onset                          | Rapid (<24 hrs)                 | Slower (over several days)      |
| Blood glucose levels           | Usually >250 mg/dL (>13.9 mmol/L) | Usually >600 mg/dL (>33.3 mmol/L) |
| Arterial pH level              | <7.3                            | Normal                          |
| Serum and urine ketones        | Present                         | Absent                          |
| Serum osmolality               | 300–350 mOsm/L                  | >350 mOsm/L                     |
| Plasma bicarbonate level       | <15 mEq/L                       | Normal                          |
| BUN and creatinine levels      | Elevated                        | Elevated                        |
| Mortality rate                 | <5%                             | 10%–40%                         |
Clinical Manifestations

The clinical picture of HHNS is one of hypotension, profound dehydration (dry mucous membranes, poor skin turgor), tachycardia, and variable neurologic signs (eg, alteration of sensorium, seizures, hemiparesis). The mortality rate ranges from 10% to 40%, usually related to an underlying illness.

Assessment and Diagnostic Findings

Diagnostic assessment includes a range of laboratory tests, including blood glucose, electrolytes, BUN, complete blood count, serum osmolality, and arterial blood gas analysis. The blood glucose level is usually 600 to 1,200 mg/dL, and the osmolality exceeds 350 mOsm/kg. Electrolyte and BUN levels are consistent with the clinical picture of severe dehydration. Mental status changes, focal neurologic deficits, and hallucinations are common secondary to the cerebral dehydration that results from extreme hyperosmolality. Postural hypotension accompanies the dehydration (ADA, Hyperglycemic Crises in Patients With Diabetes Mellitus, 2003).

Medical Management

The overall approach to the treatment of HHNS is similar to that of DKA: fluid replacement, correction of electrolyte imbalances, and insulin administration. Because of the older age of the typical patient with HHNS, close monitoring of volume and electrolyte status is important for prevention of fluid overload, heart failure, and cardiac dysrhythmias. Fluid treatment is started with 0.9% or 0.45% NS, depending on the patient’s sodium level and the severity of volume depletion. Central venous or arterial pressure monitoring guides fluid replacement. Potassium is added to IV fluids when urinary output is adequate and is guided by continuous electrocardiographic monitoring and frequent laboratory determinations of potassium.

Extremely elevated blood glucose levels drop as the patient is rehydrated. Insulin plays a less important role in the treatment of HHNS because it is not needed for reversal of acidosis, as in DKA. Nonetheless, insulin is usually administered at a continuous low rate to treat hyperglycemia, and replacement IV fluids with dextrose are administered (as in DKA) when the glucose level is decreased to the range of 250 to 300 mg/dL (13.8 to 16.6 mmol/L) (ADA, Hyperglycemic Crises in Patients With Diabetes Mellitus, 2003).

Other therapeutic modalities are determined by the underlying illness of the patient and the results of continuing clinical and laboratory evaluation. Treatment is continued until metabolic abnormalities are corrected and neurologic symptoms clear. It may take 3 to 5 days for neurologic symptoms to resolve; thus, treatment of HHNS usually continues well beyond the time when metabolic abnormalities are resolved.

After recovery from HHNS, many patients can control their diabetes with diet alone or with diet and oral antidiabetic agents. Insulin may not be needed once the acute hyperglycemic complication is resolved.

Nursing Management

Nursing care of the patient with HHNS includes close monitoring of vital signs, fluid status, and laboratory values. In addition, strategies are implemented to maintain safety and prevent injury related to changes in the patient’s sensorium secondary to HHNS. Fluid status and urine output are closely monitored because of the high risk for renal failure secondary to severe dehydration. In addition, the nurse must direct nursing care to the condition that may have precipitated the onset of HHNS. Because HHNS tends to occur in older patients, the physiologic changes that occur with aging make careful assessment of cardiovascular, pulmonary, and renal function important throughout the acute and recovery phases of HHNS (Quinn, 2001c).

NURSING PROCESS: THE PATIENT NEWLY DIAGNOSED WITH DIABETES MELLITUS

Assessment

The history and physical assessment focus on the signs and symptoms of prolonged hyperglycemia and on physical, social, and emotional factors that may affect the patient’s ability to learn and perform diabetes self-care activities. The patient is asked to describe symptoms that preceded the diagnosis of diabetes, such as polyuria, polydipsia, polyphagia, skin dryness, blurred vision, weight loss, vaginal itching, and nonhealing ulcers. The blood glucose and, for patients with type 1 diabetes, urine ketone levels are measured.

Patients with type 1 diabetes are assessed for signs of DKA, including ketonuria, Kussmaul respirations, orthostatic hypotension, and lethargy. The patient is questioned about symptoms of DKA, such as nausea, vomiting, and abdominal pain. Laboratory values are monitored for metabolic acidosis (ie, decreased pH and decreased bicarbonate level) and for electrolyte imbalance. Patients with type 2 diabetes are assessed for signs of HHNS, including hypotension, altered sensorium, seizures, and decreased skin turgor. Laboratory values are monitored for hyperosmolality and electrolyte imbalance.

If the patient exhibits signs and symptoms of DKA or HHNS, nursing care first focuses on treatment of these acute complications, as outlined in previous sections. Once these complications are resolving, nursing care then focuses on long-term management of diabetes, as discussed in this section.

Then the patient is assessed for physical factors that may impair his or her ability to learn or perform self-care skills, such as:

- Visual deficits (the patient is asked about reading ability)
- Deficits in motor coordination (the patient is observed eating or performing other tasks or handling a syringe or lanceting device)
- Neurologic deficits (eg, due to stroke, other neurologic disorders; other disabling conditions) (from history in chart; the patient is assessed for aphasia or decreased ability to follow simple commands)

The nurse evaluates the patient’s social situation for factors that may influence the diabetes treatment and education plan, such as:

- Low literacy level (may be evaluated while assessing for visual deficits by having the patient read from teaching materials)
- Limited financial resources or lack of health insurance
- Presence or absence of family support
- Typical daily schedule (patient is asked about timing and number of usual daily meals, work and exercise schedule, plans for travel)
The patient’s emotional status is assessed by observing general demeanor (eg, withdrawn, anxious) and body language (eg, avoids eye contact). The patient is asked about major concerns and fears about diabetes; this allows the nurse to assess for any misconceptions or misinformation regarding diabetes. Coping skills are assessed by asking how the patient has dealt with difficult situations in the past.

Diagnosis

NURSING DIAGNOSES
Based on the assessment data, the patient’s major nursing diagnoses may include the following:

- Risk for fluid volume deficit related to polyuria and dehydration
- Imbalanced nutrition related to imbalance of insulin, food, and physical activity
- Deficient knowledge about diabetes self-care skills/information
- Potential self-care deficit related to physical impairments or social factors
- Anxiety related to loss of control, fear of inability to manage diabetes, misinformation related to diabetes, fear of diabetes complications

COLLABORATIVE PROBLEMS/
POTENTIAL COMPLICATIONS
Based on assessment data, potential complications may include:

- Fluid overload, pulmonary edema, heart failure
- Hypokalemia
- Hyperglycemia and ketoacidosis
- Hypoglycemia
- Cerebral edema

Planning and Goals

The major goals for the patient may include maintenance of fluid and electrolyte balance, optimal control of blood glucose levels, reversal of weight loss, ability to perform survival diabetes skills and self-care activities, decreased anxiety, and absence of complications.

Nursing Interventions

MAINTAINING FLUID AND ELECTROLYTE BALANCE
Intake and output are measured. IV fluids and electrolytes are administered as prescribed, and oral fluid intake is encouraged when it is permitted. Laboratory values of serum electrolytes (especially sodium and potassium) are monitored. Vital signs are monitored for signs of dehydration (tachycardia, orthostatic hypotension).

IMPROVING NUTRITIONAL INTAKE
The diet is planned with the control of glucose as the primary goal. It must take into consideration the patient’s lifestyle, cultural background, activity level, and food preferences. An appropriate caloric intake allows the patient to achieve and maintain the desired body weight. The patient is encouraged to eat full meals and snacks as prescribed per the diabetic diet. Arrangements are made with the dietician for extra snacks before increased physical activity. It is important for the nurse to ensure that insulin orders are altered as needed for delays in eating because of diagnostic and other procedures.

REDUCING ANXIETY
The nurse provides emotional support and sets aside time to talk with the patient who wishes to express feelings, cry, or ask questions about this new diagnosis. Any misconceptions the patient or family may have regarding diabetes are dispelled (see Table 41-7). The patient and family are assisted to focus on learning self-care behaviors. The patient is encouraged to perform the skills that are feared most and must be reassured that once a skill such as self-injection or lancing a finger for glucose monitoring is performed for the first time, anxiety will decrease. Positive reinforcement is given for the self-care behaviors attempted, even if the technique is not yet completely mastered.

IMPROVING SELF-CARE
Patient teaching (discussed earlier in the Nursing Management section and below) is the major strategy used to prepare the patient for self-care. Special equipment may be needed for instruction on diabetes survival skills, such as a magnifying glass for insulin preparation or an injection-aid device for insulin injection. Low-literacy information and literature in other languages can be obtained from the ADA. The family is also taught so that they can assist in diabetes management by, for instance, prefilling syringes or monitoring the blood glucose level. The diabetes specialist is consulted regarding various blood glucose monitors and other equipment for use by patients with physical impairments. The patient is assisted in identifying community resources for education and supplies as needed. Other members of the health care team are informed about variations in the timing of meals and the work schedule (eg, if the patient works at night or in the evenings and sleeps during the day) so that the diabetes treatment regimen can be adjusted accordingly.

MONITORING AND MANAGING
POTENTIAL COMPLICATIONS

Fluid Overload
 Fluid overload can occur because of the administration of a large volume of fluid at a rapid rate that is often required to treat the patient with DKA or HHNS. This risk is increased in elderly patients and in those with preexisting cardiac disease. To avoid fluid overload and resulting congestive heart failure and pulmonary edema, the nurse monitors the patient closely during treatment by measuring vital signs at frequent intervals. Central venous pressure monitoring and hemodynamic monitoring may be initiated to provide additional measures of the fluid status. Physical examination focuses on assessment of cardiac rate and rhythm, breath sounds, venous distention, skin turgor, and urine output. The nurse monitors fluid intake and keeps careful records of IV and other fluid intake, along with urine output measurements.

Hypokalemia
As previously described, hypokalemia is a potential complication during the treatment of DKA as potassium is lost from body stores. Low serum potassium levels may result from rehydration, increased urinary excretion of potassium, and movement of potassium from the extracellular fluid into the cells with insulin administration. Prevention of hypokalemia includes cautious replacement of potassium; before its administration, however, it is
important to ensure that the patient’s kidneys are functioning. Because of the adverse effects of hypokalemia on cardiac function, monitoring of the cardiac rate, cardiac rhythm, electrocardiogram, and serum potassium levels is essential.

Hyperglycemia and Ketoacidosis
Although the hyperglycemia and ketoacidosis that may have led to the new diagnosis of diabetes may be resolved, the patient is at risk for their subsequent recurrence. Therefore, blood glucose levels and urine ketones are monitored, and medications (insulin, oral antidiabetic agents) are administered as prescribed. The patient is monitored for signs and symptoms of impending hyperglycemia and ketoacidosis; if they occur, insulin and IV fluids are administered.

Hypoglycemia
Hypoglycemia may occur if the patient skips or delays meals or does not follow the prescribed diet or greatly increases the amount of exercise without modifying diet and insulin. Also, the hospitalized patient or outpatient who fasts in preparation for diagnostic testing is at risk for hypoglycemia. Juice or glucose tablets are used for treatment of hypoglycemia. The patient is encouraged to eat full meals and snacks as prescribed per the diabetic diet. If hypoglycemia is a recurrent problem, the total therapeutic regimen should be re-evaluated.

Because of the risk of hypoglycemia, especially with intensive insulin regimens, it is important for the nurse to review with the patient its signs and symptoms, possible causes, and measures to prevent and treat it. The nurse stresses to the patient and family the importance of having information on diabetes at home for reference.

Cerebral Edema
Although the cause of cerebral edema is unknown, it is thought to be caused by rapid correction of hyperglycemia, resulting in fluid shifts. Cerebral edema can be prevented by gradual reduction in the blood glucose level (ADA, Hyperglycemic Crises in Patients With Diabetes Mellitus, 2003). An hourly flow sheet is used to enable close monitoring of the blood glucose level, serum electrolyte levels, urine output, mental status, and neurologic signs. Precautions are taken to minimize activities that could increase intracranial pressure.

PROMOTING HOME AND COMMUNITY-BASED CARE

Teaching Patients Self-Care
The patient is taught survival skills, including simple pathophysiology; treatment modalities (insulin administration, monitoring of blood glucose, and, for type 1 diabetes, urine ketones, and diet); recognition, treatment, and prevention of acute complications (hypoglycemia and hyperglycemia); and practical information (where to obtain supplies, when to call the physician). If the patient has signs of long-term diabetes complications at the time of diagnosis of diabetes, teaching about appropriate preventive behaviors (eg, foot care or eye care) should be included at this time (Chart 41-10).

Continuing Care
Follow-up education is arranged with a home care nurse or an outpatient diabetes education center. This is particularly important for the patient who has had difficulty coping with the diagnosis, the patient who has limitations that may affect his or her ability to learn or to carry out the management plan, or the patient without any family or social supports. Referral to social services and community resources (eg, centers for the visually impaired) may be needed, depending on the patient’s financial circumstances and physical limitations. The importance of self-monitoring and of monitoring and follow-up by primary health care providers is reinforced, and the patient is reminded about the importance of keeping follow-up appointments. The patient who is newly diagnosed with diabetes is also reminded about the importance of participating in other health promotion activities and health screening. Chart 41-11 is a checklist of home care skills.

---

**Chart 41-10 • PATIENT EDUCATION**

**Foot Care Tips**

1. Take care of your diabetes.
   - Work with your health care team to keep your blood glucose level within a normal range.
2. Inspect your feet every day.
   - Look at your bare feet every day for cuts, blisters, red spots, and swelling.
   - Use a mirror to check the bottoms of your feet or ask a family member for help if you have trouble seeing.
   - Check for changes in temperature.
3. Wash your feet every day.
   - Wash your feet in warm, not hot, water.
   - Dry your feet well. Be sure to dry between the toes.
   - Do not soak your feet.
   - Do not check water temperature with your feet; use a thermometer or elbow.
4. Keep the skin soft and smooth.
   - Rub a thin coat of skin lotion over the tops and bottoms of your feet, but not between your toes.
5. Smooth corns and calluses gently.
   - Use a pumice stone to smooth corns and calluses.
6. Trim your toenails each week or when needed.
   - Trim your toenails straight across and file the edges with an emery board or nail file.
7. Wear shoes and socks at all times.
   - Never walk barefoot.
   - Wear comfortable shoes that fit well and protect your feet.
   - Feel inside your shoes before putting them on each time to make sure the lining is smooth and there are no objects inside.
8. Protect your feet from hot and cold.
   - Wear shoes at the beach or on hot pavement.
   - Wear socks at night if your feet get cold.
9. Keep the blood flowing to your feet.
   - Put your feet up when sitting.
   - Wiggle your toes and move your ankles up and down for 5 minutes, 2 or 3 times a day.
   - Do not cross your legs for long periods of time.
   - Do not smoke.
10. Check with your doctor.
    - Have your doctor check your bare feet and find out whether you are likely to have serious foot problems. Remember that you may not feel the pain of an injury.
    - Call your doctor right away if a cut, sore, blister, or bruise on your foot does not begin to heal after one day.
    - Follow your doctor’s advice about foot care.
    - Do not self-medicate or use home remedies or over-the-counter agents to treat foot problems.
Evaluation

**EXPECTED PATIENT OUTCOMES**

Expected patient outcomes may include:

1. Achieves fluid and electrolyte balance
   a. Demonstrates intake and output balance
   b. Exhibits electrolyte values within normal limits
   c. Exhibits vital signs that remain stable with resolution of orthostatic hypotension and tachycardia
2. Achieves metabolic balance
   a. Avoids extremes of glucose levels (hypoglycemia or hyperglycemia)
   b. Demonstrates rapid resolution of hypoglycemic episodes
   c. Avoids further weight loss (if applicable) and begins to approach desired weight
3. Demonstrates/verbalizes diabetes survival skills
   a. Defines diabetes as a condition in which high blood glucose levels are present
   b. States normal and target blood glucose ranges
   c. Identifies factors that cause the blood glucose level to fall (insulin, exercise, some oral anti-diabetes medications)
   d. Identifies factors that cause the blood glucose level to rise (food, illness, stress, and infections)
   e. Describes the major treatment modalities: diet, exercise, monitoring, medication, education
   f. Demonstrates proper technique for drawing up and injecting insulin (including mixing two types of insulin if necessary)
   g. States dose and timing of injections, peak action and duration of insulin.
   h. Verbalizes plan for rotating insulin injection sites
   i. States dose, timing, peak action, and duration of prescribed oral agents
   j. Verbalizes understanding of food group classifications (depending on system used)
   k. Verbalizes appropriate schedule for eating snacks and meals; orders appropriate foods on menus; identifies foods that may be substituted for one another on the meal plan
   l. Demonstrates proper technique for monitoring blood glucose, including using finger-lancing device; obtaining a drop of blood; applying blood properly to strip; obtaining value of blood glucose; and recording blood glucose value. Also, is able to calibrate and clean meter, change batteries, identify alarms and warnings on meter, and use control solutions to validate strips.
m. Demonstrates proper technique for disposing of lancets and needles used for blood glucose monitoring and insulin injections (discarding them into hard plastic container such as empty bleach or detergent container or medical waste containers)

n. Demonstrates proper technique for urine ketone testing (for patients with type 1 diabetes) and verbalizes appropriate times to assess for ketones (when ill or when blood glucose test results are repeatedly and inexplicably more than 250 to 300 mg/dL [13.8 to 16.6 mmol/L])

o. Identifies community, outpatient resources for obtaining further diabetes education

p. Identifies acute complications (hypoglycemia and hyperglycemia)

q. Verbalizes symptoms of hypoglycemia (shakiness, sweating, headache, hunger, numbness or tingling of lips or fingers, weakness, fatigue, difficulty concentrating, change of mood) and dangers of untreated hypoglycemia (seizures and coma)

r. Identifies appropriate treatment of hypoglycemia, including 15 g simple carbohydrate (eg, two to four glucose tablets, 4 to 6 oz juice or soda, 2 to 3 teaspoons sugar, or 6 to 10 hard candies) followed by a snack of protein and carbohydrate (eg, cheese and crackers or milk) or by a regularly scheduled meal

s. States potential causes of hypoglycemia (too much insulin, delayed or decreased food intake, increased physical activity) and verbalizes preventive behaviors, such as frequent monitoring of blood glucose when daily schedule is changed and eating a snack before exercise

t. Verbalizes importance of wearing medical identification and carrying a source of simple carbohydrate at all times

u. Verbalizes symptoms of prolonged hyperglycemia (increased thirst and urination)

v. Verbalizes rules for sick day management

x. Describes where to purchase and store insulin, syringes, and glucose monitoring supplies

y. Identifies appropriate circumstances for calling the physician (when ill, when glucose levels repeatedly exceed a certain level [per physician guidelines], or when skin wounds fail to heal) and also identifies name of physician (or other health care team member) and 24-hour phone number

4. Absence of complications

   a. Exhibits normal cardiac rate and rhythm and normal breath sounds

   b. Exhibits jugular venous pressure and distention within normal limits

   c. Exhibits blood glucose and urine ketone levels within normal limits

   d. Exhibits no manifestations of hypoglycemia or hyperglycemia

   e. Shows improved mental status without signs of cerebral edema

   f. States measures to prevent complications

**Long-Term Complications of Diabetes**

There has been a steady decline in the number of deaths of diabetic patients attributable to ketoacidosis and infection, but an alarming rise in the number of deaths from cardiovascular and renal complications. Long-term complications are becoming more common as more people live longer with diabetes. The long-term complications of diabetes can affect almost every organ system of the body. The general categories of chronic diabetic complications are macrovascular disease, microvascular disease, and neuropathy.

The specific causes and pathogenesis of each type of complication are still being investigated. It appears, however, that increased levels of blood glucose may play a role in neuropathic disease, microvascular complications, and risk factors contributing to macrovascular complications. Hypertension may also be a major contributing factor, especially in macrovascular and microvascular diseases.

Long-term complications are seen in both type 1 and type 2 diabetes but usually do not occur within the first 5 to 10 years of the diagnosis. However, evidence of these complications may be present at the time of diagnosis of type 2 diabetes, as the patient may have had undiagnosed diabetes for many years. Renal (microvascular) disease is more prevalent among patients with type 1 diabetes, and cardiovascular (macrovascular) complications are more prevalent among older patients with type 2 diabetes.

### MACROVASCULAR COMPLICATIONS

Diabetic macrovascular complications result from changes in the medium to large blood vessels. Blood vessel walls thicken, sclerose, and become occluded by plaque that adheres to the vessel walls. Eventually, blood flow is blocked. These atherosclerotic changes are indistinguishable from atherosclerotic changes in people without diabetes, but they tend to occur more often and at an earlier age in diabetes. Coronary artery disease, cerebrovascular disease, and peripheral vascular disease are the three main types of macrovascular complications that occur more frequently in the diabetic population.

Myocardial infarction is twice as common in diabetic men and three times as common in diabetic women. There is also an increased risk for complications resulting from myocardial infarction and an increased likelihood of a second myocardial infarction. Coronary artery disease may account for 50% to 60% of all deaths in patients with diabetes. One unique feature of coronary artery disease in patients with diabetes is that the typical ischemic symptoms may be absent. Thus, patients may not experience the early warning signs of decreased coronary blood flow and may have “silent” myocardial infarctions. These silent myocardial infarctions may be discovered only as changes on the electrocardiogram. This lack of ischemic symptoms may be secondary to autonomic neuropathy (see below).

Cerebral blood vessels are similarly affected by accelerated atherosclerosis. Occlusive changes or the formation of an embolus elsewhere in the vasculature that lodges in a cerebral blood vessel can lead to transient ischemic attacks and strokes. People with diabetes have twice the risk of developing cerebrovascular disease, and studies suggest there may be a greater likelihood of death from cerebrovascular disease in patients with diabetes. In addition, recovery from a stroke may be impaired in patients who have elevated blood glucose levels at the time of and immediately after a stroke. Because symptoms of cerebrovascular disease may be similar to symptoms of acute diabetic complications (HHNS or hypoglycemia), it is very important to rapidly assess the blood glucose level (and treat abnormal levels) in patients reporting these symptoms so that testing and treatment of cerebrovascular disease (stroke) can be initiated if indicated.

Atherosclerotic changes in the large blood vessels of the lower extremities are responsible for the increased incidence (two to three times higher than in nondiabetic people) of occlusive peripheral
arterial disease in patients with diabetes. Signs and symptoms of peripheral vascular disease include diminished peripheral pulses and intermittent claudication (pain in the buttock, thigh, or calf during walking). The severe form of arterial occlusive disease in the lower extremities is largely responsible for the increased incidence of gangrene and subsequent amputation in diabetic patients. Neuropathy and impairments in wound healing also play a role in diabetic foot disease (see below).

Role of Diabetes in Macrovascular Diseases

Diabetes researchers continue to investigate the relation between diabetes and macrovascular diseases. The main feature unique to diabetes is an elevated blood glucose level; however, a direct link has not been found between hyperglycemia and atherosclerosis. Although it may be tempting to attribute the increased prevalence of macrovascular diseases to the increased prevalence of certain risk factors (eg, obesity, increased triglyceride levels, hypertension) among patients with diabetes, there is a higher-than-expected rate of macrovascular diseases among patients with diabetes when compared with nondiabetic patients with the same risk factors (ADA, Management of Dyslipidemia in Adults With Diabetes, 2003). Thus, diabetes itself is seen as an independent risk factor for the development of accelerated atherosclerosis. Other potential factors that may play a role in diabetes-related atherosclerosis include platelet and clotting factor abnormalities, decreased flexibility of red blood cells, decreased oxygen release, changes in the arterial wall related to hyperglycemia, and possibly hyperinsulinemia.

Management

Management of macrovascular complications involves prevention and treatment of the commonly accepted risk factors for atherosclerosis. Diet and exercise are important in managing obesity, hypertension, and hyperlipidemia. In addition, the use of medications to control hypertension and hyperlipidemia may be indicated. Smoking cessation is essential. Control of blood glucose levels may reduce triglyceride levels and can significantly reduce the incidence of complications.

When macrovascular complications do occur, treatment is the same as with nondiabetic patients. In addition, patients may require increased amounts of insulin or may need to switch from oral antidiabetic agents to insulin during illnesses.

MICROVASCULAR COMPLICATIONS AND DIABETIC RETINOPATHY

Although macrovascular atherosclerotic changes are seen in both diabetic and nondiabetic patients, the microvascular changes are unique to diabetes. Diabetic microvascular disease (or microangiopathy) is characterized by capillary basement membrane thickening. The basement membrane surrounds the endothelial cells of the capillary. Researchers believe that increased blood glucose levels react through a series of biochemical responses to thicken the basement membrane to several times its normal thickness. Two areas affected by these changes are the retina and the kidneys. Diabetic retinopathy is the leading cause of blindness in people between 20 and 74 years of age in the United States; it occurs in both type 1 and type 2 diabetes (ADA, Diabetic Retinopathy, 2003). Similarly, about one in every four individuals starting dialysis has diabetic nephropathy.

People with diabetes are subject to multiple visual complications (Table 41-9). The eye pathology referred to as diabetic retinopathy is caused by changes in the small blood vessels in the retina, the area of the eye that receives images and sends information about the images to the brain (Fig. 41-9). It is richly supplied with blood vessels of all kinds: small arteries and veins, arterioles, venules, and capillaries. There are three main stages of retinopathy: nonproliferative (background) retinopathy, preproliferative retinopathy, and proliferative retinopathy.

Nearly all patients with type 1 diabetes and more than 60% of patients with type 2 diabetes have some degree of retinopathy after 20 years (ADA, Diabetic Retinopathy, 2003). Changes in the microvasculature include microaneurysms, intraretinal hemorrhage, hard exudates, and focal capillary closure. Although most patients do not develop visual impairment, it can be devastating if it occurs. A complication of nonproliferative retinopathy, macular edema, occurs in approximately 10% of people with type 1 and type 2 diabetes and may lead to visual distortion and loss of central vision.

An advanced form of background retinopathy, preproliferative retinopathy, is considered a precursor to the more serious proliferative retinopathy. In preproliferative retinopathy, there

are more widespread vascular changes and loss of nerve fibers. Epidemiologic evidence suggests that 10% to 50% of patients with preproliferative retinopathy will develop proliferative retinopathy within a short time (possibly as little as 1 year). As with background retinopathy, if visual changes occur during the preproliferative stage, they are usually caused by macular edema.

Proliferative retinopathy represents the greatest threat to vision. Proliferative retinopathy is characterized by the proliferation of new blood vessels growing from the retina into the vitreous. These new vessels are prone to bleeding. The visual loss associated with proliferative retinopathy is caused by this vitreous hemorrhage and/or retinal detachment. The vitreous is normally clear, allowing light to be transmitted to the retina. When there is a hemorrhage, the vitreous becomes clouded and cannot transmit light, resulting in loss of vision. Another consequence of vitreous hemorrhage is that resorption of the blood in the vitreous leads to the formation of fibrous scar tissue. This scar tissue may place traction on the retina, resulting in retinal detachment and subsequent visual loss.

**Clinical Manifestations**

Retinopathy is a painless process. In nonproliferative and preproliferative retinopathy, blurry vision secondary to macular edema occurs in some patients, although many patients are asymptomatic. Even patients with a significant degree of proliferative retinopathy and some hemorrhaging may not experience major visual changes. However, symptoms indicative of hemorrhaging include floaters or cobwebs in the visual field, or sudden visual changes including spotty or hazy vision, or complete loss of vision. The presence of waxy-looking retinal lesions, microaneurysms of the vessels, and hemorrhages. Courtesy of American Optometric Association.

**Assessment and Diagnostic Findings**

Diagnosis is by direct visualization with an ophthalmoscope or with a technique known as fluorescein angiography. Fluorescein angiography can document the type and activity of the retinopathy. Dye is injected into an arm vein and is carried to various parts of the body through the blood, but especially through the vessels of the retina of the eye. This technique allows the ophthalmologist, using special instruments, to see the retinal vessels in bright detail and gives useful information that cannot be obtained with just an ophthalmoscope.

Side effects of this diagnostic procedure may include nausea during the dye injection; yellowish, fluorescent discoloration of the skin and urine lasting 12 to 24 hours; and occasional allergic reactions, usually manifested by hives or itching. Generally, however, it is a safe diagnostic procedure. Patient preparation includes explaining:

- The steps of the procedure
- The fact that the procedure is painless
- The potential side effects
- The type of information the technique can provide
- That the flash of the camera may be slightly uncomfortable for a short time

**Medical Management**

The first focus of management is on primary and secondary prevention. The results of the DCCT study demonstrated that maintenance of blood glucose to a normal or near-normal level in type 1 diabetes through intensive insulin therapy and patient education decreased the risk for development of retinopathy by 76% when compared with conventional therapy in patients without preexisting retinopathy. The progression of retinopathy was decreased by 54% in patients with very mild to moderate nonproliferative retinopathy at the time of initiation of treatment. Similarly, the UKPDS study demonstrated a reduced risk of retinopathy in type 2 diabetes with better control of blood glucose levels (ADA, Diabetic Retinopathy, 2003).

For advanced cases, the main treatment of diabetic retinopathy is argon laser photocoagulation. The laser treatment destroys leaking blood vessels and areas of neovascularization. For patients at increased risk for hemorrhaging, panretinal photocoagulation may significantly reduce the rate of progression to blindness. Panretinal photocoagulation involves the systematic application of multiple (more than 1,000) laser burns throughout the retina (except in the macular region). This stops the widespread growth of new vessels and hemorrhaging of damaged vessels. The role of “mild” panretinal photocoagulation (with only a third to a half as many laser burns) in the early stages of proliferative retinopathy or in patients with preproliferative changes is being investigated. For macular edema, focal photocoagulation is used to apply smaller laser burns to specific areas of microaneurysms in the macular region. This may reduce the rate of visual loss from macular edema by 50% (ADA, Diabetic Retinopathy, 2003).

Photocoagulation treatments are usually performed on an outpatient basis, and most patients can return to their usual activities by the next day. For some patients, limitations may be placed on activities involving weight bearing or bearing down. For most
patients, the treatment does not cause intense pain, although they may report varying degrees of discomfort. Usually an anesthetic eye drop is all that is needed during the treatment. A few patients may experience slight visual loss, loss of peripheral vision, or impairments in adaptation to the dark. For most patients, however, the risk of slight visual changes from the laser treatment itself is much less than the potential for loss of vision from progression of retinopathy.

When a major hemorrhage into the vitreous occurs, the vitreous fluid becomes mixed with blood and prevents light from passing through the eye; this can cause blindness. A vitrectomy is a surgical procedure in which vitreous humor filled with blood or fibrous tissue is removed with a special drill-like instrument and replaced with saline or another liquid. A vitrectomy is performed on patients who already have visual loss and in whom the vitreous hemorrhage has not cleared on its own after 6 months. The purpose is to restore useful vision; recovery to near-normal vision is not usually expected. Other strategies that may slow the progression of diabetic retinopathy include:

- Control of hypertension
- Control of blood glucose
- Cessation of smoking

Nursing Management

Nursing management of patients with diabetic retinopathy or other eye disorders involves implementing the individual plan of care and providing patient education. Education focuses on prevention through regular ophthalmologic examinations and blood glucose control and self-management of eye care regimens. The effectiveness of early diagnosis and prompt treatment is emphasized in teaching the patient and family. If vision loss occurs, nursing care must also address the patient’s adjustment to impaired vision and use of adaptive devices for diabetes self-care as well as activities of daily living. Nursing care for the patient with low vision or loss of vision is discussed in detail in Chapter 58.

PROMOTING HOME AND COMMUNITY-BASED CARE

Teaching Patients Self-Care. In all forms of therapy for retinopathy, something is destroyed in the process of saving vision, and the facts must be presented to the patient and family as honestly as possible. The course of the retinopathy may be long and stressful. In teaching and counseling the patient, it is important to stress the following:

- Retinopathy may appear after many years of diabetes, and its appearance does not necessarily mean that the diabetes is on a downhill course.
- The odds for maintaining vision are in the patient’s favor, especially with adequate control of glucose levels and blood pressure.
- Frequent eye examinations are the best way to preserve vision, because they allow for the detection of any retinopathy.

Some additional points to keep in mind when the patient with diabetes has some type of visual impairment include the following:

- Visual impairment can be a shock. The person’s response to vision loss depends on personality, self-concept, and coping mechanisms.
- As in any loss, acceptance of blindness by the patient occurs in stages; some patients may learn to accept blindness in a rather short period, and others may never do so.

- Although retinopathy occurs bilaterally, the severity may differ in the two eyes.
- Many of the chronic complications of diabetes occur simultaneously. For example, a patient who is blind due to diabetic retinopathy may also have peripheral neuropathy and may experience impairment of manual dexterity and tactile sensation.

Continuing Care. Continuing care for the patient with impaired vision due to diabetic changes depends on the severity of the impairment and the effectiveness of the patient’s coping in response to the impairment. The importance of careful diabetes management is emphasized as one means of slowing the progression of visual changes. The patient is reminded of the need to see the ophthalmologist regularly. If eye changes are progressive and unrelenting, the patient needs to be prepared for inevitable blindness. Therefore, consideration is given to making referrals for teaching the patient Braille and for training with a guide dog. Referral to state agencies should be made to ensure that the patient receives services for the blind. Family members are also taught how to assist the patient to remain as independent as possible despite decreasing visual acuity.

Referral for home care may be indicated for some patients, particularly those who live alone, those not coping well, and those who have other health problems or complications of diabetes that may interfere with their ability to perform self-care. During home visits, the nurse can assess the patient’s home environment and ability to manage diabetes despite visual impairments. Medical management and nursing care of patients with visual disturbances are discussed in detail in Chapter 58.

Nephropathy

Nephropathy, or renal disease secondary to diabetic microvascular changes in the kidney, is a common complication of diabetes. People with diabetes account for nearly half of new cases of end-stage renal disease (ESRD) each year and about a quarter of those requiring dialysis or transplantation each year in the United States. About 20% to 30% of people with type 1 or type 2 diabetes develop nephropathy, but fewer of those with type 2 diabetes progress to ESRD. Native American, Hispanic, and African-American persons with type 2 diabetes are at greater risk for ESRD than non-Hispanic whites (ADA, Diabetic Nephropathy, 2003).

Patients with type 1 diabetes frequently show initial signs of renal disease after 10 to 15 years, whereas patients with type 2 diabetes develop renal disease within 10 years of the diagnosis of diabetes. Many patients with type 2 diabetes have had diabetes for many years before it was diagnosed and treated. Therefore, they have evidence of nephropathy at the time of diagnosis.

There is no reliable method to predict whether a person will develop renal disease. The DCCT results showed that intensive treatment of diabetes with a goal of achieving a hemoglobin A1C level as close to the nondiabetic range as possible reduced the occurrence of early signs of nephropathy, such as microalbuminuria by 39%, and albuminuria by 54%. Similarly, the UKPDS study demonstrated a reduced incidence of overt nephropathy in type 2 diabetes with control of blood glucose levels (ADA, Diabetic Nephropathy, 2003).

Soon after the onset of diabetes, and especially if the blood glucose levels are elevated, the kidney’s filtration mechanism is stressed, allowing blood proteins to leak into the urine. As a result, the pressure in the blood vessels of the kidney increases. It is
thought that the elevated pressure serves as the stimulus for the development of nephropathy. Various medications and diets are being tested to prevent these complications.

**Clinical Manifestations**

Most of the signs and symptoms of renal dysfunction in the patient with diabetes are similar to those seen in patients without diabetes. (See Chap. 45 for the management of patients with renal disorders.) Also, as renal failure progresses, the catabolism (breakdown) of both exogenous and endogenous insulin decreases, and frequent hypoglycemic episodes may result. Insulin needs change as a result of changes in the catabolism of insulin, and also as a result of changes in diet related to the treatment of nephropathy. The stress of renal disease affects self-esteem, family relationships, marital relations, and virtually all aspects of daily life. As renal function decreases, the patient commonly has multiple-system failure (eg, declining visual acuity, impotence, foot ulcerations, heart failure, and nocturnal diarrhea).

**Assessment and Diagnostic Findings**

One of the most important blood proteins that leaks into the urine is albumin. Small amounts may leak undetected for years. Of patients with microalbuminuria, clinical nephropathy eventually develops in more than 85%. However, if microalbuminuria is not present, nephropathy develops in fewer than 5%. Early microalbuminuria may also be discovered in a 24-hour urine sample. The urine should be checked annually for microalbuminuria. If the microalbuminuria level exceeds 30 mg/24 hours on two consecutive tests, treatment is indicated (see Medical Management section below).

When a urine dipstick test reads consistently positive for significant amounts of albumin, serum creatinine and BUN levels are obtained. At this point in the development of renal disease, diagnostic testing for cardiac or other systemic problems may also be required. Some of the tests involve injection of special dyes that are not easily cleared by the damaged kidney, so the value of the diagnostic test must be weighed against the potential risks.

Hypertension often develops in patients (both diabetic and nondiabetic) who are in the early stages of renal disease. However, essential hypertension occurs in up to 50% of all individuals with diabetes (for unknown reasons). Thus, it should not be assumed that someone with diabetes who has hypertension also has renal disease; other diagnostic criteria must also be present.

**Medical Management**

In addition to achieving and maintaining near-normal blood glucose levels, management for all patients with diabetes should include careful attention to the following:

- Control of hypertension (the use of angiotensin-converting enzyme [ACE] inhibitors, such as captopril, because control of hypertension may also decrease or delay the onset of early proteinuria)
- Prevention or vigorous treatment of urinary tract infections
- Avoidance of nephrotoxic substances
- Adjustment of medications as renal function changes
- Low-sodium diet
- Low-protein diet

If the patient has already developed microalbuminuria and its level exceeds 30 mg/24 hours on two consecutive tests, an ACE inhibitor should be prescribed. ACE inhibitors lower blood pressure and reduce microalbuminuria and therefore protect the kidney. Alternatively, angiotensin-receptor blocking (ARB) agents may be prescribed. This preventive strategy should be part of the standard of care for the person with diabetes. Carefully designed low-protein diets also appear to reverse early leakage of small amounts of protein from the kidney (ADA, Clinical Practice Recommendations, 2003; ADA, Diabetic Nephropathy, 2003).

In chronic or end-stage renal failure, two types of treatment are available: dialysis (hemodialysis or peritoneal dialysis) and transplantation from a relative or a cadaver. Hemodialysis for the patient with diabetes is similar to that for patients without the disease (see Chap. 44). Because hemodialysis creates additional stress on patients with cardiovascular disease, it may not be appropriate for certain patients. In addition, it is extremely intrusive into a patient’s life.

Continuous ambulatory peritoneal dialysis is being used by an increasing number of patients with diabetes, mainly because of the independence it allows patients. In addition, insulin can be mixed into the dialysate, which may result in better blood glucose control and end the need for insulin injections. However, these patients may require more insulin because the dialysate contains glucose. Major risks of peritoneal dialysis are infection and peritonitis. The mortality rate for diabetic patients undergoing dialysis is higher than that in patients without diabetes undergoing dialysis and is closely related to the severity of cardiovascular problems.

Renal disease is frequently accompanied by advancing retinopathy that may require laser treatments and surgery. Severe hypertension also worsens eye disease because of the additional stress it places on the blood vessels. Patients being treated with hemodialysis who require eye surgery may be changed to peritoneal dialysis and have their hypertension aggressively controlled for several weeks before surgery. The rationale for this change is that hemodialysis requires anticoagulants that can increase the risk of bleeding after the surgery, and peritoneal dialysis minimizes pressure changes in the eyes.

The success rate for kidney transplantation in patients with diabetes has improved. In medical centers performing large numbers of transplants, the chances are 75% to 80% that the transplanted kidney will continue to function in the patient with diabetes for at least 5 years. Like the original kidneys, transplanted kidneys in patients with diabetes can eventually be damaged if blood glucose levels are consistently high after the transplantation. Therefore, monitoring blood glucose levels frequently and adjusting insulin levels in diabetic patients with transplanted kidneys are essential for long-term success. Pancreatic transplants have not been successful enough to be performed alone because of the risks associated with immunosuppression.

**DIABETIC NEUROPATHIES**

Diabetic neuropathy refers to a group of diseases that affect all types of nerves, including peripheral (sensory/motor), autonomic, and spinal nerves. The disorders appear to be clinically diverse and depend on the location of the affected nerve cells. The prevalence increases with the age of the patient and the duration of the disease and may be as high as 50% in patients who have had diabetes for 25 years.

Elevated blood glucose levels over a period of years have been implicated in the etiology of neuropathy. The pathogenesis of
neuropathy may be attributed to either a vascular or a metabolic mechanism or both, but their relative contributions have yet to be determined. Capillary basement membrane thickening and capillary closure may be present. In addition, there may be de-myelination of the nerves, which is thought to be related to hyperglycemia. Nerve conduction is disrupted when there are aberrations of the myelin sheaths. Control of blood glucose levels to normal or near-normal levels was shown in the DCCT study to decrease the incidence of neuropathy by 60%.

The two most common types of diabetic neuropathy are sensorimotor polyneuropathy and autonomic neuropathy. Cranial mononeuropathies, for example, those affecting the oculomotor nerve, also occur in diabetes, especially among the elderly. Sensorimotor polyneuropathy is a diabetic neuropathy also called peripheral neuropathy. It most commonly affects the distal portions of the nerves, especially the nerves of the lower extremities. It affects both sides of the body symmetrically and may spread in a proximal direction.

**Peripheral Neuropathy**

**CLINICAL MANIFESTATIONS**

Initial symptoms include paresthesias (prickling, tingling, or heightened sensation) and burning sensations (especially at night). As the neuropathy progresses, the feet become numb. In addition, a decrease in proprioception (awareness of posture and movement of the body and of position and weight of objects in relation to the body) and a decreased sensation of light touch may lead to an unsteady gait. Decreased sensations of pain and temperature place patients with neuropathy at increased risk for injury and undetected foot infections. Deformities of the foot may also occur, with neuropathy-related joint changes producing Charcot joints. These joint deformities result from the abnormal weight distribution on joints due to lack of proprioception.

On physical examination, a decrease in deep tendon reflexes and vibratory sensation is found. For patients who have few or no symptoms of neuropathy, these physical findings may be the only indication of neuropathic changes. For patients with signs or symptoms of neuropathy, it is important to rule out other possible neuropathies, including alcohol-induced or vitamin-deficiency neuropathies.

**MANAGEMENT**

The results of the DCCT study demonstrate that intensive insulin therapy and control of blood glucose levels delay the onset and slow the progression of neuropathy. Pain, particularly of the lower extremities, is a disturbing symptom in some people with neuropathy secondary to diabetes. For some patients, neuropathic pain spontaneously resolves within 6 months. For other patients, pain persists for many years. Various approaches to pain management can be tried. These include analgesics (preferably nonopioid); tricyclic antidepressants; phenytoin, carbamazepine, or gabapentin (antiseizure medications); mexiletine (an anti-arrhythmic); or transcutaneous electrical nerve stimulation (TENS).

The use of aldose reductase inhibitors is under study to determine whether they block the damaging effects of hyperglycemia. The topical medication capsaicin (Axscain) also has been shown in preliminary reports to decrease lower-extremity neuropathic pain. Studies of the role of this topical medication in neuropathy continue.

**Autonomic Neuropathies**

Neuropathy of the autonomic nervous system results in a broad range of dysfunctions affecting almost every organ system of the body. Three manifestations of autonomic neuropathy are related to the cardiac, GI, and renal systems. Cardiovascular symptoms range from fixed, slightly tachycardic heart rate; orthostatic hypotension; and silent, or painless, myocardial ischemia and infarction. Delayed gastric emptying may occur with the typical symptoms of early satiety, bloating, nausea, and vomiting. In addition, there may be unexplained wide swings in blood glucose levels related to inconsistent absorption of the glucose from ingested foods secondary to the inconsistent gastric emptying. “Diabetic” constipation or diarrhea (especially nocturnal diarrhea) may occur as a result.

Urinary retention, a decreased sensation of bladder fullness, and other urinary symptoms of neurogenic bladder result from autonomic neuropathy. Patients with a neurogenic bladder are predisposed to developing urinary tract infections due to inability to completely empty the bladder. This is especially true in patients with poorly controlled diabetes, because hyperglycemia impairs resistance to infection.

**HYPOGLYCEMIC UNAWARENESS**

Autonomic neuropathy of the adrenal medulla is responsible for diminished or absent adrenergic symptoms of hypoglycemia. Patients may report that they no longer feel the typical shakiness, sweating, nervousness, and palpitations associated with hypoglycemia. Strict blood glucose monitoring, including frequent SMBG, is recommended for these patients. Their inability to detect and treat these warning signs of hypoglycemia puts them at risk for developing dangerously low blood glucose levels. Therefore, their goals for blood glucose levels may need to be adjusted to reduce the risk for hypoglycemia. The patient and family need to be taught to recognize subtle signs and symptoms of hypoglycemia (Tkacs, 2002).

**SUDOMOTOR NEUROPATHY**

This neuropathic condition refers to a decrease or absence of sweating (anhidrosis) of the extremities, with a compensatory increase in upper body sweating. Dryness of the feet increases the risk for the development of foot ulcers.

**SEXUAL DYSFUNCTION**

Sexual dysfunction, especially impotence in men, is a complication of diabetes. The effects of autonomic neuropathy on female sexual functioning are not well documented. Reduced vaginal lubrication has been mentioned as a possible neuropathic effect; other possible changes in sexual function in women with diabetes include decreased libido and lack of orgasm. Vaginal infection, increased in incidence in women with diabetes, may be associated with decreased lubrication and vaginal itching and tenderness. Urinary tract infections and vaginitis may also affect sexual function (Tilton, 1997).

Impotence (inability of the penis to become rigid and sustain an erection adequate for penetration) occurs with greater frequency in diabetic men than in nondiabetic men of the same age. However, diabetic neuropathy is not the only cause of impotence in men with diabetes. Medications such as antihypertensive agents, psychological factors, and other medical conditions (eg, vascular insufficiency) that may affect nondiabetic men also play a role in impotence in diabetic men.
Some men with autonomic neuropathy have normal erectile function and can experience orgasm but do not ejaculate. Retrograde ejaculation occurs: seminal fluid is propelled backward through the posterior urethra and into the urinary bladder. Examination of the urine confirms the diagnosis because of the large number of active sperm present. Fertility counseling is necessary for couples attempting conception.

MANAGEMENT
Management strategies depend on the symptoms. There is no treatment for painless cardiac ischemia, and the prognosis is poor. Detection, however, is important so that education about avoiding strenuous exercise can be provided. Orthostatic hypotension may respond to a diet high in sodium, the discontinuation of medications that impede autonomic nervous system responses, the use of sympathomimetics and other agents (eg, caffeine) that stimulate an autonomic response, and the use of lower-body elastic garments that maximize venous return and prevent pooling of blood in the extremities.

Treatment of delayed gastric emptying includes a low-fat diet, frequent small meals, close blood glucose control, and use of agents that increase gastric motility (eg, metoclopramide, bethanechol). Treatment of diabetic diarrhea may include bulk-forming laxatives or anti-diarrheal agents. Constipation is treated with a high-fiber diet and adequate hydration; medications, laxatives, and enemas may be necessary when constipation is severe. Management of the patient with a neurogenic bladder is discussed in Chapter 44.

Treatment of sudomotor dysfunction focuses on education about skin care and heat intolerance. Erectile dysfunction is discussed in Chapter 49.

FOOT AND LEG PROBLEMS
From 50% to 75% of lower extremity amputations are performed on people with diabetes. More than 50% of these amputations are thought to be preventable, provided patients are taught foot care measures and practice them on a daily basis (ADA, Preventive Foot Care in People With Diabetes, 2003). Complications of diabetes that contribute to the increased risk of foot infections include:

- Neuropathy: Sensory neuropathy leads to loss of pain and pressure sensation, and autonomic neuropathy leads to increased dryness and fissuring of the skin (secondary to decreased sweating). Motor neuropathy results in muscular atrophy, which may lead to changes in the shape of the foot.
- Peripheral vascular disease: Poor circulation of the lower extremities contributes to poor wound healing and the development of gangrene.
- Immunocompromise: Hyperglycemia impairs the ability of specialized leukocytes to destroy bacteria. Thus, in poorly controlled diabetes, there is a lowered resistance to certain infections.

The typical sequence of events in the development of a diabetic foot ulcer begins with a soft tissue injury of the foot, formation of a fissure between the toes or in an area of dry skin, or formation of a callus (Fig. 41-10). Injuries are not felt by the patient with an insensitive foot and may be thermal (eg, from using heating pads, walking barefoot on hot concrete, or testing bath water with the foot), chemical (eg, burning the foot while using caustic agents on calluses, corns, or bunions), or traumatic (eg, injuring skin while cutting nails, walking with an undetected foreign object in the shoe, or wearing ill-fitting shoes and socks).

If the patient is not in the habit of thoroughly inspecting both feet on a daily basis, the injury or fissure may go unnoticed until a serious infection has developed. Drainage, swelling, redness (from cellulitis) of the leg, or gangrene may be the first sign of foot problems that the patient notices. Treatment of foot ulcers involves bed rest, antibiotics, and debridement. In addition, controlling glucose levels, which tend to increase when infections occur, is important for promoting wound healing. In patients with peripheral vascular disease, foot ulcers may not heal because of the decreased ability of oxygen, nutrients, and antibiotics to reach the injured tissue. Amputation may be necessary to prevent the spread of infection.

Foot assessment and foot care instructions are most important when caring for patients who are at high risk for developing foot infections. Some of the high-risk characteristics include:

- Duration of diabetes more than 10 years
- Age older than 40 years
- History of smoking
- Decreased peripheral pulses
- Decreased sensation
- Anatomic deformities or pressure areas (eg, bunions, calluses, hammer toes)
- History of previous foot ulcers or amputation

Management
Teaching patients proper foot care is a nursing intervention that can prevent costly, painful, and debilitating complications. Preventive foot care begins with careful daily assessment of the feet. The feet must be inspected on a daily basis for any redness, blisters, fissures, calluses, ulcerations, changes in skin temperature, and the development of foot deformities (ie, hammer toes, bunions). For patients with visual impairment or decreased joint mobility (especially the elderly), use of a mirror to inspect the bottom of the feet or the help of a family member in foot inspection may be necessary. The interior surfaces of shoes should be inspected for any rough spots or foreign objects.
In addition to the daily visual and manual inspection of the feet, the feet should be examined during every health care visit or at least once per year (more often if there is an increase in the patient’s risk) by a podiatrist, physician, or nurse (Fritschi, 2001). Patients with neuropathy should also undergo evaluation of neurologic status using a monofilament device by an experienced examiner (Fig. 41-11). Patients with pressure areas, such as calluses, or thick toenails should see the podiatrist routinely for treatment of calluses and trimming of nails.

Additional aspects of preventive foot care that are taught to the patient and family include the following:

- Properly bathing, drying, and lubricating the feet, taking care not to allow moisture (water or lotion) to accumulate between the toes
- Wearing closed-toe shoes that fit well. Podiatrists can provide patients with inserts (orthotics) to remove pressure from pressure points on the foot. New shoes should be broken in slowly (ie, worn for 1 to 2 hours initially, with gradual increases in the length of time worn) to avoid blister formation. Patients with bony deformities may need extra-wide shoes or extra-depth shoes. High-risk behaviors should be avoided, such as walking barefoot, using heating pads on the feet, wearing open-toed shoes, soaking the feet, and shaving calluses.
- Trimming toenails straight across and filing sharp corners to follow the contour of the toe (American Association of Diabetes Educators, 1998). If patients have visual deficits or thickened toenails, a podiatrist should cut the nails.
- Reducing risk factors, such as smoking and elevated blood lipids, that contribute to peripheral vascular disease
- Avoiding home remedies or over-the-counter agents or self-medicating to treat foot problems (Fritschi, 2001)

Blood glucose control is important for avoiding decreased resistance to infections and for preventing diabetic neuropathy. The patient may be referred by the physician to a wound care center for managing persistent wounds of the feet or legs. Many wound care centers provide diabetes education; however, the patient needs to discuss recommendations for treating wounds with his or her own physician, as well as raising any questions about diabetes management.

### Special Issues in Diabetes Care

#### THE PATIENT WITH DIABETES UNDERGOING SURGERY

During periods of physiologic stress such as surgery, blood glucose levels tend to rise as a result of an increase in the level of stress hormones (epinephrine, norepinephrine, glucagon, cortisol, and growth hormone). If hyperglycemia is not controlled during surgery, the resulting osmotic diuresis may lead to excessive loss of fluids and electrolytes. Patients with type 1 diabetes also risk developing ketoacidosis during periods of stress.

Hypoglycemia is also a concern in diabetic patients undergoing surgery. This is especially a concern during the preoperative period if surgery is delayed beyond the morning in a patient who received a morning injection of intermediate-acting insulin.

There are various approaches to managing glucose control during the perioperative period. Frequent capillary glucose monitoring is essential throughout the preoperative and postoperative periods, regardless of the method used for glucose control. Examples of these approaches are as follows, although the use of IV insulin and dextrose has become widespread with the increased availability of meters for intraoperative glucose monitoring:

- The morning of surgery, all subcutaneous insulin doses are withheld (unless the blood glucose level is elevated—for example, more than 200 mg/dL [11.1 mmol/L], in which case a small dose of subcutaneous regular insulin may be prescribed). The blood glucose level is controlled during surgery with the IV infusion of regular insulin, which is balanced by an infusion of dextrose. The insulin and dextrose infusion rates are adjusted according to frequent (hourly) capillary glucose determinations. After surgery, the insulin infusion may be continued until the patient can eat. If IV insulin is
MANAGEMENT OF HOSPITALIZED DIABETIC PATIENTS

At any one time, 10% to 20% of general medical-surgical patients in the hospital have diabetes. This number may increase as elderly patients make up a greater proportion of the population. Although some hospitals may have a specialized diabetic/metabolic unit, typically patients with diabetes are admitted throughout the hospital.

Often diabetes is not the primary medical diagnosis, yet problems with the control of diabetes frequently result from changes in the patient’s normal routine or from surgery or illness. Some of the main issues pertinent to nursing care of the hospitalized diabetic patient are presented in the following section.

Self-Care Issues

All patients admitted to the hospital must relinquish control of some aspects of their daily care to the hospital staff. For the patient with diabetes who is actively involved in diabetes self-management (especially insulin dose adjustment), relinquishing control over meal timing, insulin timing, and insulin dosage may be particularly difficult. The patient may fear hypoglycemia and express much concern over possible delays in receiving attention from the nurse if hypoglycemic symptoms occur.

It is important for the nurse to acknowledge the patient’s concerns and to involve the patient as much as possible in the plan of care. If the patient disagrees with certain aspects of the nursing or medical care related to diabetes, the nurse must communicate this to other members of the health care team and, where appropriate, make changes in the plan to meet the patient’s needs. The nurse and other health care providers need to pay particular attention to patients who are successful in managing self-care, assess their self-care management skills, and encourage them to continue their self-care management if correct and appropriate.

Hyperglycemia During Hospitalization

Hyperglycemia may occur in the hospitalized patient as a result of the original illness that led to the need for hospitalization. In addition, a number of other factors may contribute to hyperglycemia, such as:

- Changes in the usual treatment regimen (eg, increased food, decreased insulin, decreased activity)
- Medications (eg, glucocorticoids such as prednisone, which are used in the treatment of a variety of inflammatory disorders)
- IV dextrose, which may be part of the maintenance fluids or may be used for the administration of antibiotics and other medications
- Overly vigorous treatment of hypoglycemia
- Mismatched timing of meals and insulin (eg, postmeal hyperglycemia may occur if short-acting insulin is administered immediately before or even after meals)

Nursing actions to correct some of these factors are important for avoiding hyperglycemia. Assessment of the patient’s usual home routine is important. The nurse should try to approximate as much as possible the home schedule of insulin, meals, and activities. Monitoring blood glucose levels has been identified by the ADA as an additional “vital sign” essential in assessing the patient’s status (ADA, Bedside Blood Glucose Monitoring in Hospitals, 2003). The results of blood glucose monitoring provide information needed to obtain orders for extra doses of insulin (at times when insulin is usually taken by the patient), an important nursing function. The insulin doses must not be withheld when blood glucose levels are normal.

Short-acting insulin is usually needed to avoid postprandial hyperglycemia (even in the patient with normal premeal glucose levels), and NPH insulin does not peak until many hours after the dose is given. IV antibiotics should be mixed in normal saline (if possible) to avoid excess infusion of dextrose (especially in the patient who is eating). It is important to avoid overly vigorous treatment of hypoglycemia, which may lead to hyperglycemia. Treatment of hypoglycemia should be based on the established hospital protocol (usually 15 g carbohydrate in the form of juice, glucose tablets, or, if necessary, 0.5 to 1 ampule of 50% dextrose administered intravenously). Extra sugar should not be added to
the juice. If the initial treatment does not increase the glucose level adequately, the same treatment may be repeated.

**Hypoglycemia During Hospitalization**

Hypoglycemia in a hospitalized patient is usually the result of too much insulin or delays in eating. Specific examples include:

- Overuse of “sliding scale” regular insulin, particularly as a supplement to regularly scheduled, twice-daily short- and intermediate-acting insulins
- Lack of dosage change when dietary intake is changed (eg, in the patient taking nothing by mouth)
- Overly vigorous treatment of hyperglycemia (eg, giving too-frequent successive doses of regular supplemental doses of regular insulin at lunch and bedtime. Hypoglycemia may occur when two insulins peak at similar times (eg, morning NPH peaks with lunchtime regular insulin and may lead to late-afternoon hypoglycemia, and dinnertime NPH peaks with bedtime regular insulin and may lead to nocturnal hypoglycemia). To avoid hypoglycemic reactions caused by delayed food intake, the nurse should arrange for a snack to be given to the patient if meals are going to be delayed because of procedures, physical therapy, or other activities.

**Common Alterations in Diet**

Dietary modifications common during hospitalization require special consideration when the patient has diabetes.

**NPO (NOTHING BY MOUTH)**

For the patient who must have nothing by mouth in preparation for diagnostic or surgical procedures, the nurse must ensure that the usual insulin dosage has been changed. These changes may include eliminating the regular insulin and giving a decreased amount (eg, half the usual dose) of intermediate-acting NPH or Lente insulin. Another approach is to use frequent (every 3 to 4 hours) dosing of regular insulin only. IV dextrose may be administered to provide calories and to avoid hypoglycemia.

Even when no food is taken, glucose levels may rise as a result of hepatic glucose production, especially in patients with type 1 diabetes and lean patients with type 2 diabetes. Further, in type 1 diabetes, elimination of the insulin dose may lead to the development of DKA. Thus, administering insulin to the patient with type 1 diabetes who is NPO is an important nursing action.

For patients with type 2 diabetes who are taking insulin, DKA does not develop when insulin doses are eliminated because the patient’s pancreas produces some insulin. Thus, skipping the insulin dose altogether when the patient has type 2 diabetes (and is receiving IV dextrose) may be safe; however, close monitoring is essential.

For patients who are NPO for extended periods, glucose testing and insulin administration should be performed at regular intervals, usually two to four times per day. Insulin regimens for the patient who is NPO for an extended period may include NPH insulin every 12 hours (with regular insulin added to the NPH, depending on the results of glucose testing) or regular insulin only every 4 to 6 hours. These patients should receive dextrose infusions to provide some calories and limit ketosis.

To prevent these problems resulting from the need to withhold food, diagnostic tests and procedures and surgery should be scheduled early in the morning if possible.

**CLEAR LIQUID DIET**

When the diet is advanced to include clear liquids, the diabetic patient will be receiving more simple carbohydrate foods, such as juice and gelatin desserts, than are usually included in the diabetic diet. It is important for hospitalized patients to maintain their nutritional status as much as possible to promote healing. Thus, the use of reduced-calorie substitutes such as diet soda or diet gelatin desserts would not be appropriate when the only source of calories is clear liquids. Simple carbohydrates, when eaten alone, cause a rapid rise in blood glucose levels; thus, it is important to try to match peak times of insulin with peaks in glucose. If a patient was receiving insulin at regular intervals while NPO, the scheduled times for glucose tests and insulin injections must be changed to match meal times.

**ENTERAL TUBE FEEDINGS**

Tube feeding formulas contain more simple carbohydrates and less protein and fat than the typical diabetic diet. This results in increased levels of glucose in the diabetic patient receiving tube feedings. It is important that insulin doses be administered at regular intervals (eg, NPH every 12 hours or regular insulin every 4 to 6 hours) when tube feedings are administered at a continuous rate. If insulin is administered at routine (prebreakfast and predinner) times, hypoglycemia during the day may result from patients receiving more insulin without more calories, and hyperglycemia may occur during the night when feedings continue but insulin action decreases.

A common cause of hypoglycemia in patients receiving continuous tube feedings and insulin is inadvertent or purposeful discontinuation of the feeding. The nurse must discuss with the medical team any plans for temporarily discontinuing the tube feeding (eg, when the patient is away from the unit). Planning ahead may allow alterations to be made in the insulin dose, or it may allow for IV dextrose to be administered. In addition, if problems with the tube feeding develop unexpectedly (eg, the patient pulls out the tube, the tube clogs, or the feeding is discontinued when residual gastric contents are found), the nurse must notify the physician, assess blood glucose levels more frequently, and administer IV dextrose if indicated.

**PARENTERAL NUTRITION**

The patient with diabetes receiving parenteral nutrition may receive both IV insulin (added to the parenteral nutrition container) and subcutaneous intermediate- or short-acting insulins. If the patient is receiving continuous parenteral nutrition, the blood glucose level should be monitored and insulin administered at regular intervals. If the parenteral nutrition is infused over a limited number of hours, subcutaneous insulin should be administered so that peak times of insulin action coincide with times of parenteral nutrition infusion.
Hygiene

The nurse caring for a hospitalized diabetic patient must focus attention on oral hygiene and skin care. Because diabetic patients are at increased risk for periodontal disease, it is important for the nurse to assist patients with daily dental care. The patient may also require assistance in keeping the skin clean and dry, especially in areas of contact between two skin surfaces (eg, groin, axilla, and, in obese women, under the breasts), where chafing and fungal infections tend to occur.

For the bedridden diabetic patient, nursing care must emphasize the prevention of skin breakdown at pressure points. The heels are particularly susceptible to breakdown because of loss of sensation of pain and pressure associated with sensory neuropathy.

Feet should be cleaned, dried, lubricated with lotion (but not between the toes), and inspected frequently. If the patient is in the supine position, pressure on the heels can be alleviated by elevating the lower legs on a pillow, with the heels positioned over the edge of the pillow. When the patient is seated in a chair, the feet should be positioned so that pressure is not placed on the heels. If the patient has a foot ulcer, it is important to provide preventive foot care to the unaffected foot as well as to carry out special care of the affected foot.

As always, every opportunity should be taken to teach the patient about diabetes self-management, including daily oral, skin, and foot care. Female diabetic patients should also be instructed about measures for the avoidance of vaginal infections, which occur more frequently when blood glucose levels are elevated. Patients often take their cues from the nurse and realize the importance of daily personal hygiene if this is emphasized during their hospitalization.

Stress

As mentioned earlier, physiologic stress, such as infections and surgery, contributes to hyperglycemia and may precipitate DKA or HHNS. Emotional stress may have a negative impact on diabetic control as well. An increase in stress hormones leads to an increase in glucose levels, especially when the intake of food and insulin remains unchanged. In addition, during periods of emotional stress, the person with diabetes may alter the usual pattern of meals, exercise, and medication. This contributes to hyperglycemia or even hypoglycemia (eg, in the patient taking insulin or oral antidiabetic agents who stops eating in response to stress).

People who have diabetes must be made aware of the potential deterioration in diabetic control that can accompany emotional stress. They must be encouraged to try to adhere to the diabetes treatment plan as much as possible during times of stress. In addition, learning strategies for minimizing stress and coping with stress when it does occur are important aspects of diabetes education.

Gerontologic Considerations

People with diabetes are living longer; therefore, both type 1 and type 2 diabetes are seen more frequently in the elderly population. Regardless of the type or duration of diabetes, the goals of diabetes treatment may need to be altered when caring for the elderly. The focus is on quality of life issues, such as maintaining independent functioning and promoting general well-being. Although striving for strict blood glucose control may not be safe or appropriate, prolonged symptomatic hyperglycemia should be avoided.

Some elderly patients cannot manage a detailed diabetes treatment plan, but the nurse must not assume that all patients older than a certain age can adhere only to the simplest regimen. Although the goal may be simply to avoid hypoglycemia and symptomatic hyperglycemia, certain patients may prefer more complex regimens that allow more flexibility in meals and daily schedule. As with all people with diabetes, individualization of the treatment plan with frequent follow-up by the health care team is important.

Some of the barriers to learning and self-care that may be seen in the elderly include decreased vision, hearing loss, memory deficits, decreased mobility and fine motor coordination, increased tremors, depression and loneliness, decreased financial resources, and limitations related to other medical illnesses. Assessing patients for these barriers as well as discussing any misconceptions or folk beliefs regarding the cause and treatment of diabetes is important in setting up a diabetes treatment plan and educational activities. Presenting brief, simplified instructions with ample opportunity for practice of skills is important. The use of special devices such as a magnifier for the insulin syringe, an insulin pen, or a mirror for foot inspection is helpful. If necessary, family members and other community resources are called on to assist with diabetes survival skills. It is preferable to teach patients or family members to test blood glucose at home; the choice of meter should be tailored to the patient’s visual and cognitive status and dexterity. Frequent evaluation of self-care skills (insulin administration, blood glucose monitoring, foot care, diet planning) is essential, especially in patients with deteriorating vision and memory.

Dietary adherence is difficult for some elderly patients because of decreased appetite, poor dentition, and decreased physical and financial ability to prepare meals. In addition, patients may be unwilling to change long-standing dietary habits. Altering the meal plan to incorporate these eating habits or other limitations may be necessary.

NURSING ALERT

Careful monitoring for diabetes complications must not be neglected in elderly patients. Hypoglycemia is especially dangerous because it may go undetected and result in falls. Dehydration is a concern in patients who have chronically elevated blood glucose levels. Assessment for long-term complications, especially eye and foot problems, is important. Avoiding blindness and amputation through early detection and treatment of retinopathy and foot ulcers may mean the difference between institutionalization and continued independent living for the elderly person with diabetes.

NURSING PROCESS: THE PATIENT WITH DIABETES AS A SECONDARY DIAGNOSIS

People with diabetes frequently seek medical attention for problems not directly related to blood glucose control. However, during the course of treatment for the primary medical diagnosis, blood glucose control may worsen. In addition, the only opportunity for some patients with diabetes to update their knowledge about diabetes self-care and prevention of complications is during hospitalization. Therefore, it is important for the nurse caring for the patient with diabetes to focus attention on diabetes, regardless of the primary problem. Further, control of blood glucose levels is important because hyperglycemia impairs resistance to certain infections and impedes wound healing.
Assessment

Assessment of the patient with diabetes with a primary problem such as cardiac disease, renal disease, cerebrovascular disease, peripheral vascular disease, surgery, or any other type of illness is the same as that for a nondiabetic patient and is described in other chapters. In addition to nursing assessment for the primary problem, assessment of the patient with diabetes must also focus on hypoglycemia and hyperglycemia, skin breakdown, and diabetes self-care skills, including survival skills and measures for prevention of long-term complications. In addition, the patient is asked about use of alternative or complementary therapies; studies have demonstrated that patients with diabetes are twice as likely as other patients to use these therapies, and some may be harmful (Egede et al., 2002).

The patient is assessed for hypoglycemia and hyperglycemia with frequent blood glucose monitoring (usually prescribed before meals and at bedtime) and with monitoring for signs and symptoms of hypoglycemia or prolonged hyperglycemia (including DKA or HHNS), as described in previous sections.

Careful assessment of the skin, especially at pressure points and on the lower extremities, is important. The skin is assessed for dryness, cracks, skin breakdown, and redness. The patient is asked about symptoms of neuropathy, such as tingling and pain or numbness of the feet. Deep tendon reflexes are assessed.

Assessment of diabetes self-care skills is performed as early as possible to determine whether the patient requires further diabetes teaching. The nurse observes the patient preparing and injecting the insulin, monitoring blood glucose, and performing foot care. (Simply questioning the patient about these skills without actually observing performance of the skills is not sufficient.) Knowledge about diet can be assessed with the help of the dietitian through direct questioning and review of patient choices on the menu. The patient is questioned regarding signs, treatment, and prevention of hypoglycemia and hyperglycemia. The patient’s knowledge of risk factors for macrovascular disease, including hypertension, increased lipids, and smoking, is assessed. The patient is asked the date of the last eye examination (including dilation of the pupil). It is also important to assess the patient’s use of preventive health measures: annual influenza vaccination (flu shot), date of last pneumonia vaccine (ADA, Immunization and the Prevention of Influenza and Pneumococcal Disease in People With Diabetes, 2003), daily dose of aspirin (unless contraindicated) (ADA, Aspirin Therapy in Diabetes, 2003), and smoking cessation (ADA, Smoking and Diabetes, 2003).

Diagnosis

NURSING DIAGNOSES

Based on the assessment data, the patient’s major nursing diagnoses may include:

- Imbalanced nutrition related to increase in stress hormones (caused by primary medical problem) and imbalances in insulin, food, and physical activity
- Risk for impaired skin integrity related to immobility and lack of sensation (caused by neuropathy)
- Deficient knowledge about diabetes self-care skills (caused by lack of basic diabetes education or lack of continuing in-depth diabetes education)

COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications may include:

- Inadequate control of blood glucose levels (hyperglycemia, hypoglycemia)
- DKA and HHNS

Planning and Goals

The major goals for the patient may include improved nutritional status, maintenance of skin integrity, ability to perform basic diabetes self-care skills as well as preventive care for the avoidance of chronic diabetes complications, and absence of complications.

Nursing Interventions

IMPROVING NUTRITIONAL STATUS

The patient’s diet is planned with the primary goal of glucose control; however, the dietary prescription must also consider the patient’s primary health problem in addition to lifestyle, cultural background, activity level, and food preferences. If alterations are needed in the patient’s diet because of the primary health problem (eg, GI problems), alternative strategies to ensure adequate nutritional intake must be implemented. The patient’s nutritional intake is monitored carefully along with blood glucose, urine ketones, and daily weight. Blood glucose records are assessed for patterns of hypoglycemia and hyperglycemia at the same time of day, and findings are reported to the physician for alteration in insulin orders. In the patient with elevated blood glucose levels that are prolonged, laboratory values and the patient’s physical condition are monitored for signs of DKA or HHNS.

MAINTAINING SKIN CARE

The skin is assessed daily for dryness or breaks. The feet are cleaned with warm water and soap. Excessive soaking of the feet is avoided. The feet are dried thoroughly, especially between the toes, and lotion is applied to the entire foot except between the toes. For bedridden patients (especially those with a history of neuropathy), the heels are elevated off the bed with a pillow placed under the lower legs and the heels resting over the edge of the pillow. Dermal ulcers are treated as indicated and prescribed. The nurse promotes optimal blood glucose control in patients with skin breakdown.

ADDRESSING KNOWLEDGE DEFICITS

Hospital admission of the patient with diabetes provides an ideal opportunity for the nurse to assess the patient’s level of knowledge about diabetes and its management. The nurse uses this opportunity to assess the patient’s understanding of diabetes management, including blood glucose monitoring, administration of medications (ie, insulin, oral agents), dietary requirements, exercise, and strategies to prevent long- and short-term complications of diabetes. The nurse also assesses the adjustment of the patient and family to diabetes and its management and identifies any misconceptions they have.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Inadequate control of blood glucose levels may hinder recovery from the immediate health problem. Blood glucose levels are
monitored, and insulin is administered as prescribed. It is important for the nurse to ensure that insulin prescribed is modified as needed to compensate for changes in the patient’s schedule or eating pattern. Treatment is given for hypoglycemia (with oral glucose) or hyperglycemia (with supplemental regular insulin no more often than every 3 to 4 hours). Blood glucose records are assessed for patterns of hypoglycemia and hyperglycemia at the same time of day, and findings are reported to the physician for modification in insulin orders. In the patient with elevated blood glucose levels that are prolonged, laboratory values and the patient’s physical condition are monitored for signs of DKA or HHNS.

Development of acute complications of diabetes secondary to inadequate control of blood glucose levels may be associated with other health care problems because of changes in activity level and diet and physiologic alterations related to the primary health problem itself. Therefore, the patient must be monitored for acute complications (hyperglycemia, hypoglycemia) and measures must be implemented for their prevention and early treatment.

PROMOTING HOME AND COMMUNITY-BASED CARE

Teaching Patients Self-Care

Even if the patient has had diabetes for many years, it is important to assess his or her knowledge and adherence to the plan of care. It may be necessary to plan and implement a teaching plan that includes basic information about diabetes, its cause and symptoms, and acute and chronic complications and their treatment. The nurse asks the patient to give repeated return demonstrations of skills that were not performed correctly during the initial assessment. The patient is taught self-care activities for the prevention of long-term complications, including foot care, eye care, and risk factor management. The nurse also reminds the patient and family about the importance of health promotion activities and recommended health screening.

Continuing Care

The patient who is hospitalized for another health problem may require referral for home care for that problem or if gaps in knowledge about self-care are uncovered. In either case, the home care nurse can use this opportunity to assess the patient’s knowledge about diabetes management and the patient’s and family’s ability to carry out that management. Teaching provided in the hospital, clinic, office, or diabetes education center is reinforced by the nurse. The home care environment is assessed to determine its adequacy for self-care and safety.

During home care visits, the nurse assesses the patient for signs and symptoms of long-term complications and assesses the patient’s and family’s techniques in blood glucose monitoring, insulin administration, and food selection. In addition, the patient and family are reminded of the importance of participating in health promotion activities as well as recommended health screening.

Evaluation

EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Achieves optimal control of blood glucose

2. Maintains skin integrity

3. Demonstrates proper technique for administering insulin or oral antidiabetic medications and assessing blood glucose

4. Demonstrates knowledge of diet through proper menu selections and identification of pattern used for selecting foods at home

5. Verbalizes signs, appropriate treatment, and prevention of hypoglycemia and hyperglycemia

6. Verbalizes behaviors that decrease the risk of foot ulcers, including wearing shoes at all times; using hand or elbow, not foot, to test temperature of bath water; avoiding use of heating pad on feet; avoiding constritive shoes; wearing new shoes for brief periods; avoiding home remedies for treatment of corns and calluses; having feet examined at every appointment with the physician; and consulting a podiatrist for regular nail care if necessary

7. States measures to control macrovascular risk factors

8. Reports absence of acute complications
1. A patient is newly diagnosed with type 1 diabetes. Identify the major nursing assessment issues and nursing interventions in each of the following situations: (1) the patient is in the first trimester of pregnancy, (2) the patient refuses to use insulin, and (3) the patient is developmentally disabled and able to understand only simple instructions.

2. A patient with type 2 diabetes is scheduled for major abdominal surgery. What modifications in nursing assessment and care before, during, and after surgery are indicated because of the diagnosis of type 2 diabetes? How would these differ if the patient had type 1 diabetes?

3. A 57-year-old patient is brought to the emergency department by his daughter because he has become drowsy and has developed slurred speech over the last hour. His daughter, who lives out of town, tells you that he has recently been diagnosed with diabetes and has been depressed ever since. She does not know how the diabetes is being managed. What assessment data would you initially obtain? What diagnostic tests and treatments would you anticipate? Provide the rationale for those tests and treatments.

4. A 48-year-old patient with three children has had diabetes for 5 years and has not adhered to the prescribed treatment regimen. He says, “My father and grandfather both died from diabetes. I don’t see any point in modifying my life if I’m going to die from diabetes anyway.” How would you approach this patient? What resources would you use? How would you alter your approach if your first efforts to convince him of the benefits of treatment were unsuccessful?

5. Your patient has diabetes, and blood glucose monitoring is recommended. Develop a plan for teaching blood glucose monitoring to him. Explain how the results of monitoring are used in the management of type 1 and type 2 diabetes. How would you modify your teaching plan if the patient is blind? If he understands little English?

Assessment and Management of Patients With Endocrine Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Describe the functions of each of the endocrine glands and their hormones.
2. Identify the diagnostic tests used to determine alterations in function of each of the endocrine glands.
3. Compare hypothyroidism and hyperthyroidism: their causes, clinical manifestations, management, and nursing interventions.
4. Develop a plan of nursing care for the patient undergoing thyroidectomy.
5. Compare hyperparathyroidism and hypoparathyroidism: their causes, clinical manifestations, management, and nursing interventions.
6. Compare Addison’s disease with Cushing’s syndrome: their causes, clinical manifestations, management, and nursing interventions.
7. Use the nursing process as a framework for care of patients with adrenal insufficiency.
8. Use the nursing process as a framework for care of patients with Cushing’s syndrome.
9. Identify the teaching needs of patients requiring corticosteroid therapy.
The nervous system and the interconnected network of glands known as the endocrine system control body systems. Disorders of the endocrine system are common and have the potential to affect the function of every organ system in the body. Understanding the function of each of the endocrine glands, and the consequences of hypofunction and hyperfunction of each gland, enables the nurse to anticipate physiologic changes and to plan interventions to address them. Nursing interventions that are essential in managing endocrine disorders are carried out in every setting from the intensive care unit to the outpatient setting and the home.

Anatomic and Physiologic Overview

The endocrine system has far-reaching effects in the human body because of its links with the nervous system and the immune system. The hormones secreted by the endocrine system are affected in large part by structures in the central nervous system, such as the hypothalamus. Other structures located in the brain, such as the pituitary gland, are endocrine glands that influence the function of a large number of other endocrine glands. The effects of hormones secreted by the endocrine system affect the nervous system and are, in turn, mediated by the nervous system. The adrenal medulla, for example, secretes a number of substances (eg, norepinephrine and epinephrine) that act as neurotransmitters. The immune system also interacts closely with the endocrine system. It responds to the introduction of foreign agents by means of chemicals (eg, interleukins, interferons) and is regulated by hormones secreted by the adrenal cortex.

In addition to the hormones secreted by the major endocrine glands, other tissues produce hormones that are secreted into body fluids and act on nearby cells and tissues. The gastrointestinal mucosa produces hormones (eg, gastrin, enterogastrone, secretin, and cholecystokinin) that are important in the digestive process. The kidneys produce erythropoietin, a hormone that stimulates the bone marrow to produce red blood cells. The white blood cells produce cytokines that actively participate in inflammatory and immune responses.

Hormones are important in regulation of the internal environment of the body and affect every aspect of life. Some hormones target specific tissues; for example, adrenocorticotropic hormone (ACTH), or corticotrophin, is secreted by the anterior pituitary gland and targets the adrenal cortex to increase the secretion of the hormones of the adrenal cortex (ie, glucocorticoids, mineralocorticoids, and androgens). Other hormones affect a wide variety of cells and tissues of the body. Thyroid hormone is one example; it affects metabolic activity of cells throughout the body.

GLANDS OF THE ENDOCRINE SYSTEM

The endocrine glands include the pituitary, thyroid, parathyroids, adrenals, pancreatic islets, ovaries, and testes (Fig. 42-1). Endocrine glands secrete their products directly into the bloodstream, which differentiates them from exocrine glands, such as sweat glands, which secrete their products through ducts onto epithelial surfaces or into the gastrointestinal tract. The hypothalamus is the link between the nervous system and the endocrine system. (Because of the unique endocrine and exocrine functions of the pancreas, pancreatic function and disorders are discussed

Glossary

- acromegaly: disease process resulting from excessive secretion of somatotropin causing progressive enlargement of peripheral body parts, commonly the face, head, hands, and feet
- Addison’s disease: chronic adrenocortical insufficiency secondary to destruction of the adrenal glands
- Addisonian crisis: acute adrenocortical insufficiency; characterized by acute hypotension, cyanosis, fever, nausea and vomiting, and the classic signs of shock; precipitated by stress or abrupt withdrawal of therapeutic glucocorticoids
- adrenalectomy: surgical removal of one or both adrenal glands.
- adrenocorticotropic hormone (ACTH): hormone secreted by the anterior pituitary, essential for growth and development
- androgens: hormones secreted by the adrenal cortex; stimulate activity of accessory male sex organs and development of male sex characteristics
- adrenogenital syndrome: masculinization in women, feminization in men, or premature sexual development in children; result of abnormal secretion of adrenocortical hormones, especially androgen
- basal metabolic rate: chemical reactions occurring when the body is at rest
- calcitonin: hormone secreted by the parafollicular cells of the thyroid gland; participates in calcium regulation
- Chvostek’s sign: spasm of the facial muscles produced by sharply tapping over the facial nerve in front of the parotid gland and anterior to the ear; causes spasm or twitching of the mouth, nose, and eye; suggestive of latent tetany in patients with hypocalcemia
- corticosteroids: hormones produced by the adrenal cortex or their synthetic equivalents; also referred to as adrenal-cortical hormone and adrenocorticosteroid; consist of glucocorticoids, mineralocorticoids, and androgens
- cretinism: stunted body growth and mental development appearing during the first year of life as a result of congenital hypothyroidism
- Cushing’s syndrome: group of symptoms produced by an excess of free circulating cortisol from the adrenal cortex; characterized by truncal obesity, “moon face,” acne, abdominal striae, and hypertension
- diabetes insipidus: condition in which abnormally large volumes of dilute urine are excreted as a result of deficient production of vasopressin
- dilutional hyponatremia: sodium deficiency developed as a result of fluid retention; associated with excessive ADH secretion in patients with SIADH
- dwarfism: generalized limited growth; condition caused by insufficient secretion of growth hormone during childhood
- endocrine: secreting internally; hormonal secretion of a ductless gland
- euthyroid: state of normal thyroid hormone production
- exocrine: secreting externally; hormonal secretion from excretory ducts
- exophthalmos: abnormal protrusion of one or both eyeballs; produces a startled expression; usually due to hyperthyroidism
- glucocorticoids: steroid hormones (ie, cortisol, cortisone, and corticosterone) secreted by the adrenal cortex in response to ACTH; produce a rise of liver glycogen and blood glucose
- Graves’ disease: a form of hyperthyroidism; characterized by a diffuse goiter, exophthalmos
- goiter: enlargement of the thyroid gland; usually caused by an iodine-deficient diet
Hashimoto’s disease: thyroiditis characterized by high levels of antimicrosomal antibodies; most common cause of hypothyroidism in the United States; also known as chronic lymphocytic thyroiditis or autoimmune thyroiditis

hormones: chemical transmitter substances produced in one organ or part of the body and carried by the bloodstream to other cells or organs on which they have a specific regulatory effect; produced mainly by endocrine glands (eg, pituitary, thyroid, gonads)

hypophysectomy: surgical removal or destruction of all or part of the pituitary gland

mineralocorticoid: steroid of the adrenal cortex; influences sodium and potassium

myxedema: severe form of hypothyroidism characterized by an accumulation of mucopolysaccharides in subcutaneous and other interstitial tissues; masklike expression, puffy eyelids, hair loss in the eyebrows, thick lips, and a broad tongue

negative feedback: regulating mechanism in which an increase or decrease in the level of a substance decreases or increases the function of the organ producing the substance

oxytocin: hormone secreted by the posterior pituitary; causes myometrial contraction at term and milk release during lactation

pheochromocytoma: chromaffin cell tumor, usually benign, located in the adrenal medulla; characterized by secretion of catecholamines resulting in hypertension, severe headache, profuse sweating, visual blurring, anxiety, and nausea

radioimmunoassay: measurement of hormone or other substance using radioisotope-labeled antigen

syndrome of inappropriate antidiuretic hormone (SIADH) secretion: excessive secretion of antidiuretic hormone (ADH) from the pituitary gland despite subnormal serum osmolality; occurs with oat cell carcinoma of the lung and other malignant tumors that produce ADH

thyroid-stimulating hormone (TSH): released from the pituitary gland; causes stimulation of the thyroid gland, resulting in release of T3 and T4

thyroid storm: severe life-threatening form of hyperthyroidism precipitated by stress; usually of abrupt onset; characterized by high fever, extreme tachycardia, and altered mental state

thyroidectomy: surgical removal of all or part of the thyroid gland

thyroiditis: inflammation of the thyroid gland; may lead to chronic hypothyroidism or resolve spontaneously

thyrotoxicosis: condition produced by excessive endogenous or exogenous thyroid hormone

thyroxine (T4): thyroid hormone; active iodoine compound formed and stored in the thyroid; deiodinated in peripheral tissues to form triiodothyronine (T3); maintains body metabolism in a steady state

triiodothyronine (T3): thyroid hormone; formed and stored in the thyroid; released in smaller quantities, biologically more active and faster onset of action than thyroxine (T4); widespread effect on cellular metabolism, influences every major organ system

Trousseau’s sign: carpopedal spasm induced when blood flow to the arm is occluded using a blood pressure cuff or tourniquet, causing ischemia to the distal nerves; suggestive sign for latent tetany in hypocalcemia

vasopressin: antidiuretic hormone secreted by the posterior pituitary; causes contraction of smooth muscle, particularly blood vessels in Chaps. 40 and 41; reproductive structures, such as the ovaries and testes, are discussed in Chaps. 47 and 49.)

FUNCTION AND REGULATION OF HORMONES

The chemical substances secreted by the endocrine glands are called hormones. Hormones help to regulate organ function in concert with the nervous system. This dual regulatory system, in which rapid action by the nervous system is balanced by slower hormonal action, permits precise control of organ functions in response to varied changes within and outside the body. Table 42-1 lists the major hormones, their target tissue, and some of their properties.

The endocrine glands are composed of secretory cells arranged in minute clusters known as acini. No ducts are present, but the glands have a rich blood supply so that the hormones they produce enter the bloodstream rapidly. In the healthy physiologic state, hormone concentration in the bloodstream is maintained at a relatively constant level. When the hormone concentration rises, further production of that hormone is inhibited. When the hormone concentration falls, the rate of production of that hormone increases. This mechanism for regulating hormone concentration in the bloodstream is called negative feedback, which is important in the regulation of many biologic processes.

CLASSIFICATION AND ACTION OF HORMONES

Hormones are classified as steroid hormones (such as hydrocortisone), peptide or protein hormones (such as insulin), and amine hormones (such as epinephrine). These different classes of hormones act on the target tissues by different mechanisms. Hormones can alter the function of the target tissue by interacting with chemical receptors located either on the cell membrane or in the interior of the cell.

Peptide and protein hormones interact with receptor sites on the cell surface, which results in the stimulation of the intracellular enzyme adenyl cyclase. This results in increased production of cyclic 3′, 5′-adenosine monophosphate (cyclic AMP). The cyclic AMP inside the cell alters enzyme activity. Thus, cyclic AMP is the “second messenger” that links the peptide hormone at the cell surface to a change in the intracellular environment. Some of the protein and peptide hormones may also act by changing membrane permeability. These hormones act within seconds or minutes. The mechanism of action for amine hormones is similar to that for peptide hormones.

Steroid hormones, because of their smaller size and higher lipid solubility, penetrate the cell membranes and interact with intracellular receptors. This steroid–receptor complex modifies cell metabolism and formation of messenger ribonucleic acid (RNA) from deoxyribonucleic acid (DNA). The messenger RNA then stimulates protein synthesis within the cell. Steroid hormones require several hours to exert their effects because they exert their action by the modification of protein synthesis.

Assessment

HEALTH HISTORY AND CLINICAL MANIFESTATIONS

Because of the widespread effects of the endocrine system on the body, a wide variety of signs and symptoms may occur with endocrine disorders. Although specific endocrine disorders are
often accompanied by specific clinical symptoms, more general manifestations may occur with a number of endocrine disorders. Changes in energy level and fatigue are common to many endocrine imbalances. During the health history, the nurse asks the patient about fatigue and changes in usual energy levels and about how the changes affect the patient’s ability to carry out activities of daily life. The nurse also asks about changes in heat and cold tolerance as well as recent changes in weight: increases or decreases may occur with changes in adrenal and thyroid disorders and may be a result of changes in fat distribution or fluid loss or retention.

Changes in sexual function and secondary sex characteristics may occur with any number of endocrine disorders and are assessed by obtaining a sexual history. Asking the patient or family about changes in mood, memory, and ability to concentrate and altered sleep patterns is important because these changes are common in endocrine disorders. Other specific symptoms that occur with specific endocrine disorders are discussed with each of those disorders.

**PHYSICAL ASSESSMENT**

The patient is observed for obvious changes in appearance that may indicate endocrine dysfunction. Changes in the skin texture are common with both hypofunction and hyperfunction of the thyroid gland. Eye changes, such as exophthalmos, may occur with hyperthyroidism and Graves’ disease. Changes in physical appearance (eg, appearance of facial hair in women, “moon face,” “buffalo hump,” thinning of the skin, obesity of the trunk and thinness of the extremities, increased size of the feet and hands, edema) may signify disorders of the thyroid, adrenal cortex, or pituitary gland.

Vital signs are measured and compared with previous values if known. Elevated blood pressure may occur with hyperfunction of the adrenal cortex or tumor of the adrenal medulla. Decreased blood pressure may occur with hypofunction of the adrenal cortex. Other specific physical assessment findings are discussed with each endocrine disorder.

**Diagnostic Evaluation**

Although a wide variety of diagnostic tests can be used in the diagnostic workup, three major categories of diagnostic tests are common: blood tests, urine tests, and stimulation and suppression tests. Specific blood tests, urine tests, and stimulation and suppression tests are discussed with the specific endocrine disorders that follow in this chapter.

</table>

Blood tests may be used to determine hormone blood levels. For example, in a patient thought to have a thyroid disorder, serum levels of thyroid-stimulating hormone (TSH) and thyroid hormone provide information about the nature (hypofunction or hyperfunction) and site (the thyroid gland, the pituitary, or the hypothalamus) of the disorder. Other blood tests are used to detect antibodies or assess the effect of the hormone on other substances (eg, the effect of insulin on blood glucose levels). Radioimmunoassays, which are radioisotope-labeled antigen tests used to measure hormones or other substances, may be performed.

Urine tests may be used to measure the amount of hormone or the end products of hormones excreted by the kidneys. One-time specimens may be obtained, or in some disorders 24-hour urine specimens are collected to measure hormones or their metabolites. For example, urinary levels of free catecholamines (norepinephrine, epinephrine, and dopamine) may be measured in patients with suspected tumors of the adrenal medulla (pheochromocytoma).

Stimulation and suppression tests may be used to diagnose endocrine disorders. Stimulation tests can determine how an endocrine gland responds to the administration of stimulating hormones that are normally produced or released by the hypothalamus or pituitary gland. If the endocrine gland responds to this stimulation, the specific disorder may be in the hypothalamus or pituitary. Failure of the endocrine gland to respond to this stimulation helps to identify the problem as being in the endocrine gland itself. Suppression tests may be used to determine whether negative feedback mechanisms that normally control secretion of hormones from the hypothalamus or pituitary gland are intact.

**Management of Patients With Pituitary Disorders**

The pituitary gland, or the hypophysis, is a round structure about 1.27 cm (½ inch) in diameter located on the inferior aspect of the brain. It is divided into the anterior, intermediate, and posterior lobes.

**PITUITARY FUNCTION AND DYSFUNCTION**

Commonly referred to as the master gland, the pituitary secretes hormones that control the secretion of hormones by other endocrine glands (Fig. 42-2). The pituitary itself is controlled by the hypothalamus, an adjacent area of the brain connected to the pituitary by the pituitary stalk.

**Posterior Pituitary**

The important hormones secreted by the posterior lobe of the pituitary gland are vasopressin (antidiuretic hormone [ADH]) and oxytocin. These hormones are synthesized in the hypothalamus and travel from the hypothalamus to the posterior pituitary gland for storage. Vasopressin controls the excretion of water by the kidney; its secretion is stimulated by an increase in the osmolality of the blood or by a decrease in blood pressure. Oxytocin facilitates milk ejection during lactation and increases the force of uterine contractions during labor and delivery. Oxytocin secretion is stimulated during pregnancy and at childbirth.

**Anterior Pituitary**

The major hormones of the anterior pituitary gland are follicle-stimulating hormone (FSH), luteinizing hormone (LH), prolactin, ACTH, thyroid-stimulating hormone (TSH), and growth hormone (also referred to as somatotropin). The secretion of these major hormones is controlled by releasing factors secreted by the hypothalamus. These releasing factors reach the anterior pituitary by way of the bloodstream in a special circulation called the pituitary portal blood system. Other hormones include melanocyte-stimulating hormone and beta-lipotropin; the function of lipotropin is poorly understood.

The hormones released by the anterior pituitary enter the general circulation and are transported to their target organs. The main function of TSH, ACTH, FSH, and LH is the release of hormones from other endocrine glands. Prolactin acts on the breast to stimulate milk production. Growth hormone has widespread effects on many target tissues and is discussed later. Hormones that stimulate other organs and tissues are discussed in conjunction with their target organs.

Growth hormone is a protein hormone that increases protein synthesis in many tissues, increases the breakdown of fatty acids in adipose tissue, and increases the glucose level in the blood. These actions of growth hormone are essential for normal growth, although other hormones, such as thyroid hormone and insulin, are required as well. Stress, exercise, and low blood glucose levels increase the secretion of growth hormone. The half-life of growth hormone activity in the blood is 20 to 30 minutes; the hormone is largely inactivated in the liver.

**Pathophysiology**

Abnormalities of pituitary function are caused by oversecretion or undersecretion of any of the hormones produced or released by the gland. Abnormalities of the anterior and posterior portions of the gland may occur independently. Oversecretion (hypersecretion) most commonly involves ACTH or growth hormone and results in Cushing’s syndrome or acromegaly, respectively. Acromegaly, an excess of growth hormone in adults, results in bone and soft tissue deformities and enlargement of the viscera without an increase in height. In children, oversecretion of growth hormone results in gigantism, with a person reaching 7 or even 8 feet tall. Conversely, insufficient secretion of growth hormone during childhood results in generalized limited growth and dwarfism.

Undersecretion (hyposecretion) commonly involves all of the anterior pituitary hormones and is termed panhypopituitarism. In this condition, the thyroid gland, the adrenal cortex, and the gonads atrophy (shrink) because of loss of the trophic-stimulating hormones.

The most common disorder related to posterior lobe dysfunction is diabetes insipidus, a condition in which abnormally large volumes of dilute urine are excreted as a result of deficient production of vasopressin.

**HYPOPITUITARISM**

Hypofunction of the pituitary gland (hypopituitarism) can result from disease of the pituitary gland itself or of the hypothalamus, but the result is essentially the same. Hypopituitarism may result from destruction of the anterior lobe of the pituitary gland. Panhypopituitarism (Simmonds’ disease) is total absence of all pituitary secretions and is rare. Postpartum pituitary necrosis (Sheehan’s syndrome) is another uncommon cause of failure of the anterior pituitary. It is more likely to occur in women with severe blood loss, hypovolemia, and hypotension at the time of delivery.
Hypopituitarism is also a complication of radiation therapy to the head and neck area. The total destruction of the pituitary gland by trauma, tumor, or vascular lesion removes all stimuli that are normally received by the thyroid, the gonads, and the adrenal glands. The result is extreme weight loss, emaciation, atrophy of all endocrine glands and organs, hair loss, impotence, amenorrhea, hypometabolism, and hypoglycemia. Coma and death occur if the missing hormones are not replaced.

**PITUITARY TUMORS**

Pituitary tumors are usually benign, although their location and effects on hormone production by target organs can cause life-threatening effects. Three principal types of pituitary tumors represent an overgrowth of (1) eosinophilic cells, (2) basophilic cells, or (3) chromophobic cells (ie, cells with no affinity for either eosinophilic or basophilic stains).

**Clinical Manifestations**

Eosinophilic tumors that develop early in life result in gigantism. The affected person may be more than 7 feet tall and large in all proportions, yet so weak and lethargic that he or she can hardly stand. If the disorder begins during adult life, the excessive skeletal growth occurs only in the feet, the hands, the superciliary ridge, the molar eminences, the nose, and the chin, giving rise to the clinical
Assessment and Diagnostic Findings

Diagnostic evaluation requires a careful history and physical examination, including assessment of visual acuity and visual fields. Computed tomography (CT) and magnetic resonance imaging (MRI) are used to diagnose the presence and extent of pituitary tumors. Serom levels of pituitary hormones may be obtained along with measurements of hormones of target organs (eg, thyroid, adrenal) to assist in diagnosis if other information is inconclusive.

Medical Management

Surgical removal of the pituitary tumor through a transsphenoidal approach is the usual treatment. Stereotactic radiation therapy, which requires use of a neurosurgery-type stereotactic frame, may be used to deliver external-beam radiation therapy precisely to the pituitary tumor with minimal effect on normal tissue (see Chap. 16). Other treatments include conventional radiation therapy, bromocriptine (dopamine antagonist), and octreotide (synthetic analog of growth hormone). These medications inhibit the production or release of growth hormone and may bring about marked improvement of symptoms. Octreotide (Sandostatin) may also be used preoperatively to improve the patient’s clinical condition and to shrink the tumor.

SURGICAL MANAGEMENT: HYPOPHYSECTOMY

Hypophysectomy, or removal of the pituitary gland, may be performed to treat primary pituitary gland tumors. It is the treatment of choice in patients with Cushing’s syndrome due to excessive production of ACTH by a tumor of the pituitary gland. Hypophysectomy may also be performed on occasion as a palliative measure to relieve bone pain secondary to metastasis of malignant lesions of the breast and prostate.

Several approaches are used to remove or destroy the pituitary gland: surgical removal by transfrontal, subcranial, or oronasal–transsphenoidal approaches or irradiation or cryosurgery. (See Chap. 61 for the transsphenoidal approach to the removal of a pituitary tumor and for the nursing management of a patient undergoing cranial surgery.) Even if surgery succeeds at removing the tumor, many of the features or symptoms of acromegaly will be unaffected (Sachse, 2001).

Clinical Manifestations

Without the action of ADH on the distal nephron of the kidney, an enormous daily output of very dilute, water-like urine with a specific gravity of 1.001 to 1.005 occurs. The urine contains no abnormal substances such as glucose and albumin. Because of the intense thirst, the patient tends to drink 2 to 20 liters of fluid daily and craves cold water. In the hereditary form of diabetes insipidus, the primary symptoms may begin at birth. In adults, the onset of diabetes insipidus may be abrupt or insidious.

The disease cannot be controlled by limiting fluid intake because the high-volume loss of urine continues even without fluid replacement. Attempts to restrict fluids cause the patient to experience an insatiable craving for urine and to develop hypernatremia and severe dehydration.

Assessment and Diagnostic Findings

The fluid deprivation test is carried out by withholding fluids for 8 to 12 hours or until 3% to 5% of the body weight is lost. The patient is weighed frequently during the test. Plasma and urine osmolality studies are performed at the beginning and end of the test. The inability to increase the specific gravity and osmolality of the urine is characteristic of diabetes insipidus. The patient continues to excrete large volumes of urine with low specific gravity and experiences weight loss, rising serum osmolality, and elevated serum sodium levels. The patient’s condition needs to be monitored frequently during the test, and the test is terminated if tachycardia, excessive weight loss, or hypotension develops.

Other diagnostic procedures include concurrent measurements of plasma levels of ADH (vasopressin) and plasma and urine osmolality, a trial of desmopressin (synthetic vasopressin) therapy and intravenous infusion of hypertonic saline solution. When the diagnosis is confirmed and the cause is not obvious (eg, head injury), the patient is carefully assessed for tumors that may be causing the disorder.

Medical Management

The objectives of therapy are (1) to replace ADH (which is usually a long-term therapeutic program), (2) to ensure adequate fluid replacement, and (3) to identify and correct the underlying
intracranial pathology. Nephrogenic causes require different management approaches.

**PHARMACOLOGIC THERAPY**

Desmopressin (DDAVP), a synthetic vasopressin without the vascular effects of natural ADH, is particularly valuable because it has a longer duration of action and fewer adverse effects than other preparations previously used to treat the disease. It is administered intranasally; the patient sprays the solution into the nose through a flexible calibrated plastic tube. One or two administrations daily or every 12 to 24 hours usually control the symptoms (Tierney, McPhee, & Papadakis, 2001).

Another form of therapy is the intramuscular administration of ADH, or vasopressin tannate in oil, which is used when the intranasal route is not possible. It is administered every 24 to 96 hours. The vial of medication should be warmed or shaken vigorously before administration. The injection is administered in the evening so that maximum results are obtained during sleep. Abdominal cramps are a side effect of this medication. Rotation of injection sites is necessary to prevent lipodystrophy.

Clofibrate, a hypolipidemic agent, has been found to have an antidiuretic effect on patients with diabetes insipidus who have some residual hypothalamic vasopressin. Chlorpropamide (Diabinese) and thiazide diuretics are also used in mild forms of the disease because they potentiate the action of vasopressin. The patient receiving chlorpropamide should be warned of the possibility of hypoglycemic reactions.

If the diabetes insipidus is renal in origin, the previously described treatments are ineffective. Thiazide diuretics, mild salt depletion, and prostaglandin inhibitors (ibuprofen, indomethacin, and aspirin) are used to treat the nephrogenic form of diabetes insipidus.

**Nursing Management**

The patient with possible diabetes insipidus needs encouragement and support while undergoing studies for a possible cranial lesion. The nurse needs to inform the patient and family about follow-up care and emergency measures. The nurse also needs to provide specific verbal and written instructions, show the patient how to administer the medications, and observe return demonstrations as appropriate. The nurse also advises the patient to wear a medical identification bracelet and to carry medication and instructions of procedures and treatments assist the patient to deal for the patient at risk for SIADH. Supportive measures and explanations of procedures and treatments assist the patient to deal with this disorder (Terpstra & Terpstra, 2000).

**SYNDROME OF INAPPROPRIATE ANTI DIURETIC HORMONE SECRETION**

The syndrome of inappropriate antidiuretic hormone (SIADH) secretion includes excessive growth hormone (ADH) secretion from the pituitary gland even in the face of subnormal serum osmolality. Patients with this disorder cannot excrete a dilute urine. They retain fluids and develop a sodium deficiency known as dilutional hyponatremia. SIADH is often of nonendocrine origin; for instance, the syndrome may occur in patients with bronchogenic carcinoma in which malignant lung cells synthesize and release ADH. SIADH has also occurred with severe pneumonia, pneumothorax, and other disorders of the lungs, in addition to malignant tumors that affect other organs (Terpstra & Terpstra, 2000).

Disorders of the central nervous system, such as head injury, brain surgery or tumor, and infection, are thought to produce SIADH by direct stimulation of the pituitary gland. Some medications (vincristine, phenothiazines, tricyclic antidepressants, thiazide diuretics, and others) and nicotine have been implicated in SIADH; they either directly stimulate the pituitary gland or increase the sensitivity of renal tubules to circulating ADH.

Eliminating the underlying cause, if possible, and restricting fluid intake are typical interventions for managing this syndrome. Because retained water is excreted slowly through the kidneys, the extracellular fluid volume contracts and the serum sodium concentration gradually increases toward normal. Diuretics (eg, furosemide [Lasix]) may be used along with fluid restriction if severe hyponatremia is present.

Close monitoring of fluid intake and output, daily weight, urine and blood chemistries, and neurologic status is indicated for the patient at risk for SIADH. Supportive measures and explanations of procedures and treatments assist the patient to deal with this disorder (Terpstra & Terpstra, 2000).

**Management of Patients With Thyroid Disorders**

The thyroid gland is a butterfly-shaped organ located in the lower neck anterior to the trachea (Fig. 42-3). It consists of two lateral lobes connected by an isthmus. The gland is about 5 cm long and 3 cm wide and weighs about 30 g. The blood flow to the thyroid is very high (about 5 mL/min per gram of thyroid tissue), about five times the blood flow to the liver. This reflects the high metabolic activity of the thyroid gland. The thyroid gland produces three hormones: thyroxine (T4), triiodothyronine (T3), and calcitonin. Thyroxine and triiodothyronine are referred to collectively as thyroid hormone.

**THYROID FUNCTION AND DYSFUNCTION**

Various hormones and chemicals are responsible for normal thyroid function. Key among them are thyroid hormone, calcitonin, and iodine.

**Thyroid Hormone**

The two separate hormones, thyroxine (T4) and triiodothyronine (T3), that are produced by the thyroid gland and that make up thyroid hormone, are amino acids that have the unique property of...
containing iodine molecules bound to the amino acid structure. \( T_4 \) contains four iodine atoms in each molecule, and \( T_3 \) contains only three. These hormones are synthesized and stored bound to proteins in the cells of the thyroid gland until needed for release into the bloodstream. About 75% of bound thyroid hormone is bound to thyroxine-binding globulin (TBG); the remaining bound thyroid hormone is bound to thyroid-binding prealbumin and albumin.

**ROLE OF IODINE**

Iodine is essential to the thyroid gland for synthesis of its hormones. In fact, the major use of iodine in the body is by the thyroid, and the major derangement in iodine deficiency is alteration of thyroid function. Iodide is ingested in the diet and absorbed into the blood in the gastrointestinal tract. The thyroid gland is extremely efficient in taking up iodide from the blood and concentrating it within the cells, where iodide ions are converted to iodine molecules, which react with tyrosine (an amino acid) to form the thyroid hormones.

**REGULATION OF THYROID HORMONE**

The secretion of \( T_3 \) and \( T_4 \) by the thyroid gland is controlled by thyroid-stimulating hormone (TSH, or thyrotropin) from the anterior pituitary gland. TSH controls the rate of thyroid hormone release. In turn, the level of thyroid hormone in the blood determines the release of TSH. If thyroid hormone concentration in the blood decreases, the release of TSH increases, which causes increased output of \( T_3 \) and \( T_4 \). This is an example of negative feedback.

Thyrotropin-releasing hormone (TRH), secreted by the hypothalamus, exerts a modulating influence on the release of TSH from the pituitary. Environmental factors, such as a decrease in temperature, may lead to increased secretion of TRH, resulting in elevated secretion of thyroid hormones. Figure 42-4 shows the hypothalamic-pituitary-thyroid axis, which regulates thyroid hormone production.

**FUNCTION OF THYROXINE AND TRIIODOTHYRONINE**

The primary function of the thyroid hormone is to control the cellular metabolic activity. \( T_4 \), a relatively weak hormone, maintains body metabolism in a steady state. \( T_3 \) is about five times as potent as \( T_4 \) and has a more rapid metabolic action. These hormones accelerate metabolic processes by increasing the level of specific enzymes that contribute to oxygen consumption and altering the responsiveness of tissues to other hormones. The thyroid hormones influence cell replication and are important in brain development. Thyroid hormone is also necessary for normal growth. The thyroid hormones, through their widespread effects on cellular metabolism, influence every major organ system.

**Calcitonin**

Calcitonin, or thyrocalcitonin, is another important hormone secreted by the thyroid gland. It is secreted in response to high plasma levels of calcium, and it reduces the plasma level of calcium by increasing its deposition in bone.

**Assessment and Diagnostic Findings**

The thyroid gland is inspected and palpated routinely on all patients. Inspection begins with identification of landmarks. The lower neck region between the sternocleidomastoid muscles is inspected for swelling or asymmetry. The patient is instructed to extend the neck slightly and swallow. Thyroid tissue rises normally with swallowing. The thyroid is then palpated for size, shape, consistency, symmetry, and the presence of tenderness.

The examiner may examine the thyroid from an anterior or a posterior position. In the posterior position, both hands encircle the patient’s neck. The thumbs rest on the nape of the neck, while the index and middle fingers palpate for the thyroid isthmus and the anterior surfaces of the lateral lobes. When palpable, the isthmus is perceived as firm and of a rubber-band consistency.

The left lobe is examined by positioning the patient so that the neck flexes slightly forward and to the left. The thyroid cartilage is then displaced to the left with the fingers of the right hand. This maneuver displaces the left lobe deep into the sternocleidomastoid muscle, while the index and middle fingers exert opposite pressure in the anterior portion of the muscle. Having the patient swallow during the maneuver may assist the examiner to locate the thyroid as it ascends in the neck. The procedure is reversed to examine the right lobe. The isthmus is the only portion of the thyroid that is normally palpable. If a patient has a very thin neck, two thin, smooth, nontender lobes may also be palpable.

If palpation discloses an enlarged thyroid gland, both lobes are auscultated using the diaphragm of the stethoscope. Auscultation identifies the localized audible vibration of a bruit. This abnormal finding indicates increased blood flow through the thyroid gland and necessitates referral to a physician. Tenderness, enlargement, and nodularity within the thyroid also require referral for additional evaluation (Table 42-2).
**THYROID FUNCTION TESTS**

Assessment measures in addition to palpation and auscultation include thyroid function tests, such as laboratory measurement of thyroid hormones, thyroid scanning, biopsy, and ultrasonography. The most widely used tests are serum immunoassay for TSH and free thyroxine (FT₄). Measurement of TSH has a sensitivity and specificity of greater than 95% (Larson, Anderson & Koslawy, 2000). FT₄ levels correlate with metabolic status and are elevated in hyperthyroidism and decreased in hypothyroidism.

**THYROID-STIMULATING HORMONE**

Measurement of the serum TSH concentration is the single best screening test of thyroid function in outpatients because of its high sensitivity. The ability to detect minute changes in serum TSH makes it possible to distinguish subclinical thyroid disease from euthyroid states in patients with low or high normal values. Values above the normal range of 0.4 to 6.15 µU/mL indicate primary hypothyroidism, and low values indicate hyperthyroidism. When the TSH is normal, there is a 98% chance that the FT₄ is also normal. Measurement of TSH is also used for monitoring thyroid hormone replacement therapy and for differentiating between disorders of the thyroid gland itself and disorders of the pituitary or hypothalamus. Current recommendations suggest TSH screening for all adults beginning at age 35, and every 5 years thereafter (Ladenson, Singer, Ain, et al., 2000).

**SERUM FREE THYROXINE**

The test most commonly used to confirm an abnormal TSH is FT₄. FT₄ is a direct measurement of free (unbound) thyroxine, the only metabolically active fraction of T₄. The range of FT₄ in serum is normally 0.9 to 1.7 ng/dL (11.5 to 21.8 pmol/L). When measured by the dialysis method, FT₄ is not affected by variations in protein binding and is the procedure of choice for following the changes in T₄ secretion during treatment of hyperthyroidism. Measurement of FT₄ by the immunoassay technique is less reliable because it may be affected by medication, illness, or changes in protein binding. An estimate (or index) of FT₄ can also be calculated by multiplying total T₄ by T₃ resin uptake.

**SERUM T₃ AND T₄**

Measurement of total T₃ or T₄ includes protein-bound and free hormone levels that occur in response to TSH secretion. T₄ is 80% bound to thyroxine-binding globulin (TBG); T₃ is bound less firmly. Only 0.03% of T₄ and 0.3% of T₃ is unbound. Any factor that alters binding proteins also changes the T₃ and T₄ levels. Serious systemic illnesses, medications (eg, oral contraceptives, corticosteroids, phenytoin, salicylates), and protein wasting as a result of nephrosis and use of androgens may interfere with accurate test results. Normal range for T₄ is 4.5 to 11.5 µg/dL (58.5 to 150 nmol/L). Although serum T₃ and T₄ levels generally increase or decrease together, the T₃ level appears to be a more accurate indicator of hyperthyroidism, which causes a greater rise in T₃ than T₄ levels. The normal range for serum T₃ is 70 to 220 ng/dL (1.15 to 3.10 nmol/L).

**T₃ RESIN UPTAKE TEST**

The T₃ resin uptake test is an indirect measure of unsaturated TBG. Its purpose is to determine the amount of thyroid hormone bound to TBG and the number of available binding sites. This provides an index of the amount of thyroid hormone already present in the circulation. Normally, TBG is not fully saturated with thyroid hormone, and additional binding sites are available to combine with radioiodine-labeled T₃ added to the blood specimen. The normal T₃ uptake value is 25% to 35% (relative uptake fraction, 0.25 to 0.35), which indicates that about one third of the available sites of TBG are occupied by thyroid hormone. If the number of free or unoccupied binding sites is low, as in hyperthyroidism, the T₃ uptake is greater than 35% (0.35). If the number of available sites is high, as occurs in hypothyroidism, the test results are less than 25% (0.25). T₃ uptake is useful in the evaluation of thyroid hormone levels in patients who have received diagnostic or therapeutic doses of radioiodine.

iodine. The test results may be altered by the use of estrogens, androgens, salicylates, phenytoin, anticoagulants, or corticosteroids.

THYROID AUTIMMUNE ANTIbODIES
Autoimmune thyroid diseases include both hypothyroid and hyperthyroid conditions. Results of testing by immunoassay techniques for antithyroid antibodies, specifically antimicrosomal antibodies, are positive in chronic autoimmune thyroid disease (90%), Hashimoto’s thyroiditis (100%), Graves’ disease (80%), and other organ-specific autoimmune disease, such as lupus erythematosus, and rheumatoid arthritis. Antithyroid antibody titers are normally present in 5% to 10% of the population and increase with age.

RADIOACTIVE IODINE UPTAKE
The radioactive iodine uptake test measures the rate of iodine uptake by the thyroid gland. The patient is administered a tracer dose of iodine-123 (123I) or another radionuclide, and a count is made over the thyroid gland with use of a scintillation counter, which detects and counts the gamma rays released from the breakdown of 123I in the thyroid. It measures the proportion of the administered dose present in the thyroid gland at a specific time after its administration. It is a simple test and provides reliable results. It is affected by the patient’s intake of iodide or thyroid hormone; therefore, a careful preliminary clinical history is essential in evaluating results. Normal values vary from one geographic region to another and with the intake of iodine. Patients with hyperthyroidism exhibit a high uptake of the 123I (in some patients, up to 90%), whereas patients with hypothyroidism exhibit a very low uptake. This test is also used to determine what dose of 123I should be administered to treat a patient with hyperthyroidism.

FINE-NEEDLE ASPIRATION BIOPSY
Using a small-gauge needle to sample the thyroid tissue for biopsy is a safe and accurate method of detecting malignancy. It is often the initial test for evaluation of thyroid masses. Results are reported as (1) negative (benign), (2) positive (malignant), (3) indeterminate (suspicious), and (4) inadequate (nondiagnostic).

THYROID SCAN, RADIOSCAN, OR SCINTISCAN
In a thyroid scan, a scintillation detector or gamma camera moves back and forth across the area to be studied in a series of parallel tracks, and a visual image is made of the distribution of radioactivity in the area being scanned. Although 123I has been the most commonly used isotope, several other radioactive isotopes, including technetium-99m (99mTc) pertechnetate, thallium, and americium, are also used. Scans are helpful in determining the location, size, shape, and anatomic function of the thyroid gland, particularly when thyroid tissue is subternal or large. Identifying areas of increased function (“hot” areas) or decreased function (“cold” areas) can assist in diagnosis. Although most areas of decreased function do not represent malignancies, lack of function increases the likelihood of malignancy, particularly if only one nonfunctioning area is present. Scanning of the entire body, to obtain the total body profile, may be carried out in a search for a functioning thyroid metastasis.

OTHER DIAGNOSTIC TESTS
Ultrasound, CT scans, and MRI may be used to clarify or confirm the results of other diagnostic studies. Thyroglobulin (Tg), a precursor for T3 and T4, can be measured reliably in the serum by radioimmunoassay. Clinically, it is used to detect persistence or recurrence of thyroid carcinoma.

NURSING IMPLICATIONS
When thyroid tests are scheduled, it is necessary to determine whether the patient has taken medications or agents that contain iodine because these may alter the test results. Iodine-containing medications include contrast agents and those used to treat thyroid disorders. Less obvious sources of iodine are topical antiseptics, multivitamin preparations, and food supplements frequently found in health food stores; cough syrups; and amiodarone, an antiarrhythmic agent. Other medications that may affect test results are estrogens, salicylates, amphetamines, chemotherapeutic agents, antibiotics, corticosteroids, and mercurial diuretics. The nurse asks the patient about the use of these medications and notes their use on the laboratory requisition. Chart 42-1 gives a partial list of agents that may interfere with accurate testing of thyroid gland function.

ABNORMAL THYROID FUNCTION
Inadequate secretion of thyroid hormone during fetal and neonatal development results in stunted physical and mental growth (cretinism) because of general depression of metabolic activity. In adults, hypothyroidism manifests as lethargy, slow movement, and generalized slowing of body functions.

Oversecretion of thyroid hormones (hyperthyroidism) is manifested by a greatly increased metabolic rate. Many of the other characteristics of hyperthyroidism result from the increased response to circulating catecholamines (epinephrine and norepinephrine). Hypothyroidism and hyperthyroidism are discussed in detail in the following sections of this chapter.

Oversecretion of thyroid hormones is usually associated with an enlarged thyroid gland (goiter). Goiter also commonly occurs with iodine deficiency. In this latter condition, lack of iodine results in low levels of circulating thyroid hormones, which causes increased release of TSH; the elevated TSH causes overproduction of thyroglobulin and hypothyrophy of the thyroid gland. The term euthyroid refers to thyroid hormone production that is within normal limits.

HYPOTHYROIDISM
Hypothyroidism results from suboptimal levels of thyroid hormone. Thyroid deficiency can affect all body functions and can range from mild, subclinical forms to myxedema, an advanced form. The most common cause of hypothyroidism in adults is autoimmune thyroiditis (Hashimoto’s disease), in which the immune system attacks the thyroid gland. Symptoms of hypo-

thyroidism may later be followed by those of hypothyroidism and myxedema. Hypothyroidism also commonly occurs in patients with previous hyperthyroidism who have been treated with radioactive iodine or antithyroid medications or who have had surgery. It occurs most frequently in older women. Radiation therapy for head and neck cancer can also cause hypothyroidism in older men; therefore, testing of thyroid function is recommended for all patients who receive such treatment. Other causes of hypothyroidism are presented in Chart 42-2.

Pathophysiology

More than 95% of patients with hypothyroidism have primary or thyroidal hypothyroidism, which refers to dysfunction of the thyroid gland itself. When thyroid dysfunction is caused by failure of the pituitary gland, the hypothalamus, or both, it is known as central hypothyroidism. It may be referred to as pituitary or secondary hypothyroidism if it is caused entirely by a pituitary disorder, and hypothalamic or tertiary hypothyroidism if it is attributable to a disorder of the hypothalamus resulting in inadequate secretion of TSH because of decreased stimulation by TRH. When thyroid deficiency is present at birth, the condition is known as cretinism. In such instances, the mother may also suffer from thyroid deficiency.

The term myxedema refers to the accumulation of mucopolysaccharides in subcutaneous and other interstitial tissues. Although myxedema occurs in long-standing hypothyroidism, the term is used appropriately only to describe the extreme symptoms of severe hypothyroidism.

Clinical Manifestations

Early symptoms of hypothyroidism are nonspecific, but extreme fatigue makes it difficult for the person to complete a full day’s work or participate in usual activities. Reports of hair loss, brittle nails, and dry skin are common, and numbness and tingling of the fingers may occur. Occasional, the voice may become husky, and the patient may complain of hoarseness. Menstrual disturbances such as menorrhagia or amenorrhea occur, in addition to loss of libido. Hypothyroidism affects women five times more frequently than men and occurs most often between 30 and 60 years of age.

Severe hypothyroidism results in a subnormal temperature and pulse rate. The patient usually begins to gain weight even with an increase in food intake, although severely hypothyroid patients may be cachectic. The skin becomes thickened because of an accumulation of mucopolysaccharides in the subcutaneous tissues. The hair thins and falls out; the face becomes expressionless and masklike. The patient often complains of being cold even in a warm environment.

At first, the patient may be irritable and may complain of fatigue, but as the condition progresses, the emotional responses are subdued. The mental processes become dulled, and the patient appears apathetic. Speech is slow, the tongue enlarges, and hands and feet increase in size. The patient frequently complains of constipation. Deafness may also occur.

Advanced hypothyroidism may produce personality and cognitive changes characteristic of dementia. Inadequate ventilation and sleep apnea can occur with severe hypothyroidism. Pleural effusion, pericardial effusion, and respiratory muscle weakness may also occur.

Severe hypothyroidism is associated with an elevated serum cholesterol level, atherosclerosis, coronary artery disease, and poor left ventricular function. The patient with advanced hypothyroidism is hypothermic and abnormally sensitive to sedatives, opioids, and anesthetic agents. Therefore, these medications are administered only with extreme caution.

Patients with unrecognized hypothyroidism who are undergoing surgery are at increased risk for intraoperative hypotension and postoperative heart failure and altered mental status.

Myxedema coma describes the most extreme, severe stage of hypothyroidism, in which the patient is hypothermic and unconscious. Myxedema coma may follow increasing lethargy, progressing to stupor and then coma. Undiagnosed hypothyroidism may be precipitated by infection or other systemic disease or by use of sedatives or opioid analgesics. The patient’s respiratory drive is depressed, resulting in alveolar hypventilation, progressive CO₂ retention, narcosis, and coma. These symptoms, along with cardiovascular collapse and shock, require aggressive and intensive therapy if the patient is to survive. Even with early vigorous therapy, however, mortality is high.

Gerontologic Considerations

Most patients with primary hypothyroidism are 40 to 70 years of age and present with long-standing mild to moderate hypothyroidism. Subclinical disease is common among older women and can be asymptomatic or mistaken for other medical conditions. Subtle symptoms of hypothyroidism, such as fatigue, muscle aches, and mental confusion, may be attributed to the normal aging process by the patient, family, and health care provider. The higher prevalence of hypothyroidism in elderly people may be related to alterations in immune function with age. Regular screening of TSH levels is recommended for people older than 60 because they are at high risk for hypothyroidism (Ladenson et al., 2000).

The signs and symptoms of hypothyroidism are often atypical in elderly people; the elderly patient may have few or no symptoms until the dysfunction is severe. Depression, apathy, or decreased mobility or activity may be the major initial symptom. The major symptoms of hypothyroidism may be depression and apathy, and may be accompanied by significant weight loss. One fourth of affected elderly patients experience constipation.

### Chart 42-2

**Causes of Hypothyroidism**

- Chronic lymphocytic thyroiditis (Hashimoto’s thyroiditis)
- Atrophy of thyroid gland with aging
- Therapy for hyperthyroidism
  - Radioactive iodine (¹³¹I)
  - Thyroidectomy
  - Medications
    - Lithium
  - Iodine compounds
  - Antithyroid medications
- Radiation to head and neck for treatment of head and neck cancers, lymphoma
- Infiltrative diseases of the thyroid (amyloidosis, scleroderma)
- Iodine deficiency and iodine excess

**NURSING ALERT** In all patients with hypothyroidism, the effects of analgesic agents, sedatives, and anesthetic agents are prolonged; particular caution is necessary in administering these agents to elderly patients because of concurrent changes in liver and renal function.
Medical Management

The primary objective in the management of hypothyroidism is to restore a normal metabolic state by replacing the missing hormone.

PHARMACOLOGIC THERAPY

Synthetic levothyroxine (Synthroid or Levothroid) is the preferred preparation for treating hypothyroidism and suppressing nontoxic goiters. The dosage for hormone replacement is based on the patient’s serum TSH concentration. Desiccated thyroid is used less frequently because it often results in transient elevated serum concentrations of T3, with occasional symptoms of hyperthyroidism. If replacement therapy is adequate, the symptoms of myxedema disappear and normal metabolic activity is resumed.

Prevention of Cardiac Dysfunction. Any patient who has had hypothyroidism for a long period is almost certain to have elevated serum cholesterol levels, atherosclerosis, and coronary artery disease. As long as metabolism is subnormal and the tissues, including the myocardium, require relatively little oxygen, a reduction in blood supply is tolerated without overt symptoms of coronary artery disease. When thyroid hormone is administered, however, the oxygen demand increases, but oxygen delivery cannot be increased unless, or until, the atherosclerosis improves. This occurs very slowly, if at all. The occurrence of angina is the signal that the oxygen needs of the myocardium exceed its blood supply. Angina or dysrhythmias may occur when thyroid replacement is initiated because thyroid hormones enhance the cardiovascular effects of catecholamines.

NURSING ALERT The nurse must monitor for myocardial ischemia or infarction, which may occur in response to therapy in patients with severe, long-standing hypothyroidism or myxedema coma. The nurse must also be alert for signs of angina, especially during the early phase of treatment; if detected, it must be reported and treated at once to avoid a fatal myocardial infarction.

Obviously, if angina or dysrhythmias occur, thyroid hormone administration must be discontinued immediately. Later, when it can be resumed safely, thyroid hormone replacement should be prescribed cautiously at a lower dosage and under the close observation of the physician and the nurse.

Prevention of Medication Interactions. Precautions must be taken during the course of therapy because of the interaction of thyroid hormones with other medications. Thyroid hormones may increase blood glucose levels, which may necessitate adjustment in the dosage of insulin or oral antidiabetic agents in patients with diabetes. The effects of thyroid hormone may be increased by phenytoin (Dilantin) and tricyclic antidepressant agents. Thyroid hormones may also increase the pharmacologic effects of digitalis glycosides, anticoagulant agents, and indomethacin, requiring careful observation and assessment by the nurse for side effects. Bone loss and osteoporosis may also occur with thyroid therapy.

NURSING ALERT Severe untreated hypothyroidism is characterized by an increased susceptibility to the effects of all hypnotic and sedative agents.

Even in small doses, hypnotic and sedative agents may induce profound somnolence, lasting far longer than anticipated. Moreover, they are likely to cause respiratory depression, which can easily be fatal because of decreased respiratory reserve and alveolar hypoventilation. If their use is necessary, the dose is one-half or one-third that ordinarily prescribed in patients of similar age and weight with normal thyroid function. If these medications must be used, the patient must be monitored closely for signs of impending narcosis (stupor-like condition) or respiratory failure.

Gerontologic Considerations

In the elderly patient with mild to moderate hypothyroidism, thyroid hormone replacement must be started with low dosages and increased gradually to prevent serious cardiovascular and neurologic side effects. Angina, for example, may occur with rapid thyroid replacement in the presence of coronary artery disease secondary to the hypothyroid state. Heart failure and tachydysrhythmias may worsen during the transition from the hypothyroid state to the normal metabolic state. Dementia may become more apparent during early thyroid hormone replacement in the elderly patient.

Elderly patients with severe hypothyroidism and atherosclerosis may also become confused and agitated if their metabolic rates are raised too quickly. Marked clinical improvement follows the administration of hormone replacement; such medication must be continued for life, even though signs of hypothyroidism disappear within 3 to 12 weeks.

Myxedema and myxedema coma generally occur exclusively in patients older than 50 years. The high mortality rate of myxedema coma mandates immediate intravenous administration of high doses of thyroid hormone as well as supportive care.

SUPPORTIVE THERAPY

In severe hypothyroidism and myxedema coma, management includes maintaining vital functions. Arterial blood gases may be measured to determine CO2 retention and to guide the use of assisted ventilation to combat hypoventilation. Pulse oximetry may also be helpful in monitoring oxygen saturation levels. Fluids are administered cautiously because of the danger of water intoxication. Application of external heat (eg, heating pads) is avoided because it increases oxygen requirements and may lead to vascular collapse. If hypoglycemia is evident, concentrated glucose may be prescribed to provide glucose without precipitating fluid overload. Thyroid hormone (usually Synthroid) is administered intravenously until consciousness is restored if myxedema has progressed to myxedema coma. The patient is then continued on oral thyroid hormone therapy. Because of an associated adrenocortical insufficiency, corticosteroid therapy may be necessary.

Nursing Management

Nursing care of the patient with hypothyroidism and myxedema is summarized in the Plan of Nursing Care.

MODIFYING ACTIVITY

The patient with hypothyroidism experiences decreased energy and moderate to severe lethargy. As a result, the risk for complications from immobility increases. The patient’s ability to exercise and participate in activities is further limited by the changes in cardiovascular and pulmonary status secondary to hypothyroidism. A major role of the nurse is assisting with care and hygiene while encouraging the patient to participate in activities within established tolerance levels to prevent the complications of immobility.
## Plan of Nursing Care
### Care of the Patient With Hypothyroidism

<table>
<thead>
<tr>
<th>Nursing Interventions</th>
<th>Rationale</th>
<th>Expected Outcomes</th>
</tr>
</thead>
</table>
| **Nursing Diagnosis:** Activity intolerance related to fatigue and depressed cognitive process  
**Goal:** Increased participation in activities and increased independence | | |
| 1. Promote independence in self-care activities.  
a. Space activities to promote rest and exercise as tolerated.  
b. Assist with self-care activities when patient is fatigued.  
c. Provide stimulation through conversation and nonstressful activities.  
d. Monitor patient’s response to increasing activities.  
   | 1. Encouragement needed in fatigued, often depressed patient  
a. Encourages activities while allowing time for adequate rest  
b. Permits patient to participate to the extent possible in self-care activities  
c. Promotes interest without overly stressing the patient  
d. Guards against over- and under-exertion by the patient  
   | • Participates in self-care activities  
• Reports decreased level of fatigue  
• Displays interest and awareness in environment  
• Participates in activities and events in environment  
• Participates in family events and activities  
• Reports no chest pain, increased fatigue, or breathlessness with increased level of activity  |

| Nursing Diagnosis: Risk for imbalanced body temperature  
**Goal:** Maintenance of normal body temperature | | |
| 1. Provide extra layer of clothing or extra blanket.  
2. Avoid and discourage use of external heat source (eg, heating pads, electric or warming blankets).  
3. Monitor patient’s body temperature and report decreases from patient’s baseline value.  
4. Protect from exposure to cold and drafts.  
   | 1. Minimizes heat loss  
2. Reduces risk of peripheral vasodilation and vascular collapse  
3. Detects decreased body temperature and onset of myxedema coma  
4. Increases patient’s level of comfort and decreases further heat loss  
   | • Experiences relief of discomfort and cold intolerance  
• Maintains baseline body temperature  
• Reports adequate feeling of warmth and lack of chilling  
• Uses extra layer of clothing or extra blanket  
• Explains rationale for avoiding external heat source  |

| Nursing Diagnosis: Constipation related to depressed gastrointestinal function  
**Goal:** Return of normal bowel function | | |
| 1. Encourage increased fluid intake within limits of fluid restriction.  
2. Provide foods high in fiber.  
3. Instruct patient about foods with high water content.  
5. Encourage increased mobility within patient’s exercise tolerance.  
6. Encourage patient to use laxatives and enemas sparingly.  
   | 1. Promotes passage of soft stools  
2. Increases bulk of stools and more frequent bowel movements  
3. Provides rationale for patient to increase fluid intake  
4. Permits detection of constipation and return to normal bowel pattern  
5. Promotes evacuation of the bowel  
6. Minimizes patient’s dependence on laxatives and enemas and encourages normal pattern of bowel evacuation  
   | • Reports normal bowel function  
• Identifies and consumes foods high in fiber  
• Drinks recommended amount of fluid each day  
• Participates in gradually increasing exercises  
• Uses laxatives as prescribed and avoids excessive dependence on laxatives and enemas  |

| Nursing Diagnosis: Deficient knowledge about the therapeutic regimen for lifelong thyroid replacement therapy  
**Goal:** Knowledge and acceptance of the prescribed therapeutic regimen | | |
| 1. Explain rationale for thyroid hormone replacement.  
2. Describe desired effects of medication to patient.  
3. Assist patient to develop schedule and checklist to ensure self-administration of thyroid replacement.  
   | 1. Provides rationale for patient to use thyroid hormone replacement as prescribed  
2. Provides encouragement to patient by identifying improved physical status and well-being that will occur with thyroid hormone therapy and return to a euthyroid state  
3. Increases chances that medication will be taken as prescribed  
   | • Describes therapeutic regimen correctly  
• Explains rationale for thyroid hormone replacement  
• Identifies positive outcomes of thyroid hormone replacement  
• Administers medication to self as prescribed  |

MONITORING PHYSICAL STATUS
The nurse closely monitors the patient’s vital signs and cognitive level to detect the following:
- Deterioration of physical and mental status
- Signs and symptoms indicating that treatment has resulted in the metabolic rate exceeding the ability of the cardiovascular and pulmonary systems to respond
- Continued limitations or complications of myxedema

NURSING ALERT Medications are administered to the patient with hypothyroidism with extreme caution because of the potential for altered metabolism and excretion and depressed metabolic rate and respiratory status.

PROMOTING PHYSICAL COMFORT
The patient often experiences chilling and extreme intolerance to cold, even if the room feels comfortable or hot to others. Extra clothing and blankets are provided, and the patient is protected from drafts. Use of heating pads and electric blankets is avoided because of the risk of peripheral vasodilation, further loss of body heat, and vascular collapse. Additionally, the patient could be burned by these items without being aware of it because of delayed responses and decreased mental status.

PROMOTING EMOTIONAL SUPPORT
The patient with moderate to severe hypothyroidism may experience severe emotional reactions to changes in appearance and body image and the frequent delay in diagnosis. The nonspecific, early symptoms may produce negative reactions by family members and friends, and the family and friends may have labeled the patient mentally unstable, uncooperative, or unwilling to participate in self-care activities.

As hypothyroidism is treated successfully and symptoms subside, the patient may experience depression and guilt as a result of the progression and severity of symptoms that occurred. The nurse informs the patient and family that the symptoms and inability to recognize them are common and part of the disorder itself. The patient and family may require assistance and counseling to deal with the emotional concerns and reactions that result.

PROMOTING HOME AND COMMUNITY-BASED CARE
Teaching Patients Self-Care. Because most hypothyroidism treatment takes place at home, the patient and family require information and instruction that will enable them to monitor the patient’s condition and response to therapy. The nurse instructs the patient about the desired actions and side effects of medications and about how and when to take prescribed medications. The importance of continuing to take medications as prescribed even after symptoms improve is stressed to the patient. Because of the slowed mental processes that occur with hypothyroidism, it is important that a family member also be informed and instructed about treatment goals, medication schedules, and side effects to be reported to the physician. The nurse provides written instructions and guidelines for the patient and family.

Dietary instruction is provided to promote weight loss once medication has been initiated and to promote return of normal bowel patterns. The patient and family are often very concerned about the changes they have observed as a result of the hypothyroid state. It is often reassuring to the patient and family to be informed that many of the symptoms will disappear with effective treatment (Chart 42-3).

Continuing Care. The patient with hypothyroidism and myxedema coma needs considerable follow-up and health care. Before hospital discharge, arrangements are made to ensure that the patient returns to an environment that will promote adherence to the prescribed treatment plan. Assistance in devising a schedule or record ensures accurate and complete administration of medications. The nurse reinforces the importance of continued thyroid hormone replacement and periodic follow-up testing and instructs the patient and family members about the signs of overmedication and undermedication.

If indicated, a referral is made for home care. The home care nurse assesses the patient’s progress toward recovery and ability to cope with the recent changes, along with the patient’s physical and cognitive status and the patient’s and family’s understanding of the importance of prescribed long-term medication therapy and compliance with the medication schedule and recommended follow-up tests and appointments. The nurse documents, and reports to the patient’s primary health care provider, subtle signs and symptoms that may indicate either inadequate or excessive thyroxine hormone.
Hyperthyroidism

Hyperthyroidism is the second most prevalent endocrine disorder, after diabetes mellitus. Graves’ disease, the most common type of hyperthyroidism, results from an excessive output of thyroid hormones caused by abnormal stimulation of the thyroid gland by circulating immunoglobulins. It affects women eight times more frequently than men, with onset usually between the second and fourth decades (Tierney et al., 2001). It may appear after an emotional shock, stress, or an infection, but the exact significance of these relationships is not understood. Other common causes of hyperthyroidism include thyroiditis and excessive ingestion of thyroid hormone.

Clinical Manifestations

Patients with well-developed hyperthyroidism exhibit a characteristic group of signs and symptoms (sometimes referred to as thyrotoxicosis). The presenting symptom is often nervousness. These patients are often emotionally hypervigilant, irritable, and apprehensive; they cannot sit quietly; they suffer from palpitations; and their pulse is abnormally rapid at rest as well as on exertion. They tolerate heat poorly and perspire unusually freely. The skin is flushed continuously, with a characteristic salmon color, and is likely to be warm, soft, and moist. Elderly patients, however, may report dry skin and diffuse pruritus. A fine tremor of the hands may be observed. Patients may exhibit exophthalmos (bulging eyes), which produces a startled facial expression.

Other manifestations include an increased appetite and dietary intake, progressive weight loss, abnormal muscular fatigability and weakness (difficulty in climbing stairs and rising from a chair), amenorrhea, and changes in bowel function. The pulse rate ranges constantly between 90 and 160 beats/min; the systolic, but characteristically not the diastolic, blood pressure is elevated; atrial fibrillation may occur; and cardiac decompensation in the form of heart failure is common, especially in elderly patients. Osteoporosis and fracture are also associated with hyperthyroidism.

Cardiac effects may include sinus tachycardia or dysrhythmias, increased pulse pressure, and palpitations; it has been suggested that these changes may be related to increased sensitivity to catecholamines or to changes in neurotransmitter turnover. Myocardial hypertrophy and heart failure may occur if the hyperthyroidism is severe and untreated.

The course of the disease may be mild, characterized by remissions and exacerbations and terminating with spontaneous recovery in a few months or years. Conversely, it may progress relentlessly, with the untreated person becoming emaciated, intensely nervous, delirious, and even disoriented; eventually, the heart fails.

Symptoms of hyperthyroidism may occur with the release of excessive amounts of thyroid hormone as a result of inflammation after irradiation of the thyroid or destruction of thyroid tissue by tumor. Such symptoms may also occur with excessive administration of thyroid hormone for treatment of hypothyroidism. Long-standing use of thyroid hormone in the absence of close monitoring may be a cause of symptoms of hyperthyroidism. It is also likely to result in premature osteoporosis, particularly in women.

Assessment and Diagnostic Findings

The thyroid gland invariably is enlarged to some extent. It is soft and may pulsate; a thrill often can be palpated, and a bruit is heard over the thyroid arteries. These are signs of greatly increased blood flow through the thyroid gland. In advanced cases, the diagnosis is made on the basis of the symptoms and an increase in serum T₄ and an increased ¹²³I or ¹²⁵I uptake by the thyroid in excess of 50%.

Gerontologic Considerations

The elderly patient requires periodic follow-up monitoring of serum TSH levels because poor compliance with therapy may occur or the patient may take the medications erratically. A careful history may identify the need for further teaching about the importance of the medication. Because of the prevalence of hypothyroidism, testing of serum TSH levels in elderly people every 5 years has been recommended (Smallridge, 2000). In addition, the patient is reminded of the importance of participating in general health promotion activities and recommended health screening.
Gerontologic Considerations

Although hyperthyroidism is much less common in elderly people than hypothyroidism, patients older than 60 years account for 10% to 15% of the cases of thyrotoxicosis. Although some older patients develop typical signs and symptoms of thyrotoxicosis, in most an atypical picture is present, which is often subclinical (Toft, 2001).

Elderly patients commonly present with vague and nonspecific signs and symptoms, making disorders hard to detect. Symptoms such as tachycardia, fatigue, mental confusion, weight loss, change in bowel habits, and depression can be attributed to age and other illnesses common to elderly people. In addition, the patient may report cardiovascular symptoms and difficulty climbing stairs or rising from a chair because of muscle weakness. New or worsening heart failure or angina is more likely to occur in elderly than in younger patients. The elderly patient may experience a single manifestation, such as atrial fibrillation, anorexia, or weight loss. These signs and symptoms may mask the underlying thyroid disease.

Spontaneous remission of hyperthyroidism is rare in elderly patients. Measurement of TSH is indicated in elderly patients with unexplained physical or mental deterioration.

Medical Management

Treatment of hyperthyroidism is directed toward reducing thyroid hyperactivity to relieve symptoms and remove the cause of important complications. Treatment depends on the cause of the hyperthyroidism and may require a combination of therapeutic approaches.

Pharmacologic Therapy

Two forms of pharmacotherapy are available for treating hyperthyroidism and controlling excessive thyroid activity: (1) use of irradiation by administration of the radioisotope 123I or 131I for destructive effects on the thyroid gland and (2) antithyroid medications that interfere with the synthesis of thyroid hormones and other agents that control manifestations of hyperthyroidism. Surgical removal of most of the thyroid gland is a nonpharmacologic alternative.

Radioactive Iodine Therapy. The goal of radioactive iodine therapy (123I or 131I) is to destroy the overactive thyroid cells. Use of radioactive iodine is the most common treatment in elderly patients. Almost all the iodine that enters and is retained in the body becomes concentrated in the thyroid gland. Therefore, the radioactive isotope of iodine is concentrated in the thyroid gland, where it destroys thyroid cells without jeopardizing other radiosensitive tissues. Over a period of several weeks, thyroid cells exposed to the radioactive iodine are destroyed, resulting in reduction of the hyperthyroid state and inevitably hypothyroidism.

The patient is instructed about what to expect with this tasteless, colorless radiiodine, which may be administered by the radiologist. A single oral dose of the agent is administered, based on 80 to 160 µCi/g estimated thyroid weight. About 70% to 85% of patients are cured by one dose of radioactive iodine. An additional 10% to 20% require two doses; rarely is a third dose necessary. Use of an ablative dose of radioactive iodine initially causes an acute release of thyroid hormone from the thyroid gland and may cause an increase of symptoms. The patient is observed for signs of thyroid storm; propranolol is useful in controlling these symptoms.

After treatment with radioactive iodine, the patient is followed closely until the euthyroid state is reached. In 3 to 4 weeks, symptoms of hyperthyroidism subside. Because the incidence of hypothyroidism after this form of treatment is very high (ie, more than 90% at 10 years), close follow-up is required to evaluate thyroid function. Thyroid hormone replacement is necessary; small doses are usually prescribed, with the dose gradually increased over a period of months (up to about 1 year) until the FT4 and TSH levels stabilize within normal ranges.

Radioactive iodine has been used to treat toxic adenomas and multinodular goiter and most varieties of thyrotoxicosis (rarely permanently successful); it is preferred for treating patients beyond the childbearing years with diffuse toxic goiter. It is contraindicated in pregnancy and in nursing mothers because radioiodine crosses the placenta and is secreted in breast milk. A major advantage of treatment with radioactive iodine is that it avoids many of the side effects associated with antithyroid medications. However, many patients and their families fear medications that are radioactive. Because of this fear, many patients elect to take antithyroid medications rather than radioactive iodine.

Gerontologic Considerations

The use of radioactive iodine is generally recommended for treatment of thyrotoxicosis in elderly patients unless an enlarged thyroid gland is pressing on the airway. The hypermetabolic state of thyrotoxicosis must be controlled by antithyroid medications before radioactive iodine is administered because radiation may precipitate thyroid storm by increasing the release of hormone from the thyroid gland. Thyroid storm, if it occurs, has a mortality rate of 10% in elderly patients (Chart 42-4).

Antithyroid Medications. The objective of pharmacotherapy is to inhibit one or more stages in thyroid hormone synthesis or hormone release; another goal may be to reduce the amount of thyroid tissue, with resulting decreased thyroid hormone production.

Antithyroid agents block the utilization of iodine by interfering with the iodination of tyrosine and the coupling of iodothyrosines in the synthesis of thyroid hormones. This prevents the synthesis of thyroid hormone. The most commonly used medications are propylthiouracil (Propacil, PTU) or methimazole (Tapazole) until the patient is euthyroid (ie, neither hyperthyroid nor hypothyroid). These medications block extrathyroidal conversion of T4 to T3. Because antithyroid medications do not interfere with release or activity of previously formed thyroid hormones, it may take several weeks for relief of symptoms. At this time the maintenance dose is established, followed by a gradual withdrawal of the medication over the next several months.

Therapy is determined on the basis of clinical criteria, including changes in pulse rate, pulse pressure, body weight, size of the goiter, and results of laboratory studies of thyroid function.

Toxic complications of antithyroid medications are relatively uncommon; nevertheless, the importance of periodic follow-up is emphasized because medication sensitization, fever, rash, urticaria, or even agranulocytosis and thrombocytopenia (decrease in granulocytes and platelets) may develop. With any sign of infection, especially pharyngitis and fever or the occurrence of mouth ulcers, the patient is advised to stop the medication, notify the physician immediately, and undergo hematologic studies. Rash, arthralgias, and fever occur in 5% of patients. Agranulocytosis, the most serious toxic side effect, occurs in 1 of every 200 patients. Its incidence is higher in patients older than 40 years. It generally occurs within the first 3 months of therapy but may occur up to 1 year after it is started.
Thyroid storm (thyrotoxic crisis) is a form of severe hyperthyroidism, usually of abrupt onset. Untreated it is almost always fatal, but with proper treatment the mortality rate is reduced substantially. The patient with thyroid storm or crisis is critically ill and requires astute observation and aggressive and supportive nursing care during and after the acute stage of illness.

Clinical Manifestations
Thyroid storm is characterized by:
- High fever (hyperpyrexia) above 38.5°C (101.3°F)
- Extreme tachycardia (more than 130 beats/min)
- Exaggerated symptoms of hyperthyroidism with disturbances of a major system—for example, GI (weight loss, diarrhea, abdominal pain), or cardiovascular (edema, chest pain, dyspnea, palpitations)
- Altered neurologic or mental state, which frequently appears as delirium psychosis, somnolence, or coma

Life-threatening thyroid storm is usually precipitated by stress, such as injury, infection, thyroid and nonthyroid surgery, tooth extraction, insulin reaction, diabetic acidosis, pregnancy, digitalis intoxication, abrupt withdrawal of antithyroid medications, extreme emotional stress, or vigorous palpation of the thyroid. These factors can precipitate thyroid storm in the partially controlled or completely untreated patient with hyperthyroidism. Current methods of diagnosis and treatment for hyperthyroidism have greatly decreased the incidence of thyroid storm, making it uncommon today.

Management
Immediate objectives are reduction of body temperature and heart rate and prevention of vascular collapse. Measures to accomplish these objectives include:
- A hypothermia mattress or blanket, ice packs, a cool environment, hydrocortisone, and acetaminophen (Tylenol). Salicylates (eg, aspirin) are not used because they displace thyroid hormone from binding proteins and worsen the hypermetabolism.
- Humidified oxygen is administered to improve tissue oxygenation and meet the high metabolic demands. Arterial blood gas levels or pulse oximetry may be used to monitor respiratory status.
- Intravenous fluids containing dextrose are administered to replace liver glycogen stores that have been decreased in the hyperthyroid patient.
- PTU or methimazole is administered to impede formation of thyroid hormone and block conversion of $T_4$ to $T_3$, the more active form of thyroid hormone.
- Hydrocortisone is prescribed to treat shock or adrenal insufficiency.
- Iodine is administered to decrease output of $T_3$ from the thyroid gland. For cardiac problems such as atrial fibrillation, dysrhythmias, and heart failure, sympathetic agents may be administered. Propranolol, combined with digitalis, has been effective in reducing severe cardiac symptoms.

Gerontologic Considerations
If antithyroid agents are used in elderly patients, the patient must be monitored closely because elderly patients are more likely to develop granulocytopenia. The dosage of other medications to treat other chronic illnesses in elderly patients may need to be modified because of the altered rate of metabolism in hyperthyroidism.

Adjuvative Therapy. Iodine or iodide compounds, once the only therapy available for patients with hyperthyroidism, are no longer used as the sole method of treatment. Such compounds decrease the release of thyroid hormones from the thyroid gland and reduce the vascularity and size of the thyroid. Compounds such as potassium iodide (KI), Lugol’s solution, and saturated solution of potassium iodide (SSKI) may be used in combination with antithyroid agents or beta-adrenergic blockers to prepare the patient with hyperthyroidism for surgery. These agents reduce the activity of the thyroid hormone and the vascularity of the thyroid gland, making the surgical procedure safer. Solutions of iodine and iodide compounds are more palatable in milk or fruit juice and are administered through a straw to prevent staining of the teeth. These compounds reduce the metabolic rate more rapidly than antithyroid medications, but their action does not last as long.

NURSING ALERT Patients receiving these medications should be observed for the development of goiter and should be cautioned against use of over-the-counter medications that contain iodides and can increase the response to iodide therapy. Cough medications, expectorants, bronchodilators, and salt substitutes may contain iodide and should be avoided by the patient receiving iodide therapy.

Beta-adrenergic blocking agents are important in controlling the sympathetic nervous system effects of hyperthyroidism. For example, propranolol (Inderal) is used to control nervousness, tachycardia, tremor, anxiety, and heat intolerance. The patient continues taking propranolol until the FT$_4$ is within the normal range and the TSH level approaches normal.

Gerontologic Considerations
Use of beta-adrenergic blocking agents (eg, propranolol [Inderal]) may be indicated to decrease the cardiovascular and neurologic signs and symptoms of thyrotoxicosis. These agents must be used with extreme caution in elderly patients to minimize adverse effects on cardiac function that may produce heart failure.

Surgical Management
Surgery to remove thyroid tissue was once the primary method of treating hyperthyroidism; today, surgery is reserved for special circumstances—for example, in pregnant women allergic to antithyroid medications, patients with large goiters, or patients unable to take antithyroid agents. Surgery for treatment of hyperthyroidism is performed soon after the thyroid function has returned to normal (4 to 6 weeks).
The surgical removal of about five sixths of the thyroid tissue (subtotal thyroidectomy) practically ensures a prolonged remission in most patients with exophthalmic goiter. Its use today is reserved for large goiters, presence of obstructive symptoms, pregnant women, or when there is a need for rapid normalization of thyroid function (Argueta & Whitaker, 2000; Fatourechi, 2000). Before surgery, propylthiouracil is administered until signs of hyperthyroidism have disappeared. A beta-adrenergic blocking agent (propranolol) may be used to reduce the heart rate and other signs and symptoms of hyperthyroidism; however, this does not create a euthyroid state. Iodine (Lugol’s solution or potassium iodide) may be prescribed in an effort to reduce blood loss; however, the effectiveness of this is unknown. Patients receiving iodine medication must be monitored for evidence of iodine toxicity (iodism), which requires immediate withdrawal of the medication. Symptoms of iodism include swelling of the buccal mucosa, excessive salivation, coryza, and skin eruptions.

**Recurrent Hyperthyroidism**

No treatment for thyrotoxicosis is without side effects, and all three treatments (radioactive iodine therapy, antithyroid medications, and surgery) share the same complications: relapse or recurrent hyperthyroidism and permanent hypothyroidism. The rate of relapse increases in patients who had very severe disease, a long history of dysfunction, ocular and cardiac symptoms, large goiter, and relapse after previous treatment. The relapse rate after radioactive iodine therapy depends on the dose used in treatment. Patients receiving a lower dose of radioactive iodine are more likely to require subsequent treatment than those being treated with a higher dose. Hyperthyroidism occurs in almost 80% of patients at 1 year and in 90% to 100% by 5 years for both the multiple low-dose and single high-dose methods.

Although rates of relapse and the occurrence of hyperthyroidism vary, relapse with antithyroid medications is about 45% by 1 year after completion of therapy and almost 75% by 5 years later (Larson et al., 2000). Discontinuation of antithyroid medications before therapy is complete usually results in relapse within 6 months in most patients. The incidence of relapse with subtotal thyroidectomy is 19% at 18 months; an incidence of hypothyroidism is 25% and has been reported at 18 months after surgery. The risk for these complications illustrates the importance of long-term follow-up of patients treated for hyperthyroidism.

**NURSING DIAGNOSES**

Based on all the assessment data, the major nursing diagnoses of the patient with hyperthyroidism include the following:

- Imbalanced nutrition, less than body requirements, related to exaggerated metabolic rate, excessive appetite, and increased gastrointestinal activity
- Ineffective coping related to irritability, hyperexcitability, apprehension, and emotional instability
- Low self-esteem related to changes in appearance, excessive appetite, and weight loss
- Altered body temperature

**POTENTIAL COMPLICATIONS**

Based on assessment data, potential complications may include the following:

- Thyrotoxicosis or thyroid storm
- Hypothyroidism

**Planning and Goals**

The goals for the patient may be improved nutritional status, improved coping ability, improved self-esteem, maintenance of normal body temperature, and absence of complications.

**Nursing Interventions**

**IMPROVING NUTRITIONAL STATUS**

Hyperthyroidism affects all body systems, including the gastrointestinal system. The appetite is increased but may be satisfied by several well-balanced meals of small size, even up to six meals a day. Foods and fluids are selected to replace fluid lost through diarrhea and diaphoresis and to control the diarrhea that results from increased peristalsis. Rapid movement of food through the gastrointestinal tract may result in nutritional imbalance and further weight loss. To reduce diarrhea, highly seasoned foods and stimulants such as coffee, tea, cola, and alcohol are discouraged. High-calorie, high-protein foods are encouraged. A quiet atmosphere during mealtime may aid digestion. Weight and dietary intake are recorded to monitor nutritional status.

**ENHANCING COPING MEASURES**

The patient with hyperthyroidism needs reassurance that the emotional reactions being experienced are a result of the disorder and that with effective treatment those symptoms will be controlled. Because of the negative effect these symptoms have on family and friends, they too need reassurance that these symptoms are expected to disappear with treatment.

It is important to use a calm, unhurried approach with the patient. Stressful experiences are minimized; therefore, if hospitalized, the patient is not placed in a room with very ill or talkative patients. The environment is kept quiet and uncluttered. Noises, such as loud music, conversation, and equipment alarms, are minimized. The nurse encourages relaxing activities if they do not overstimulate the patient.

**THE PATIENT WITH HYPERTHYROIDISM**

**Assessment**

The health history and examination focus on symptoms related to accelerated or exaggerated metabolism. These include the patient’s and family’s report of irritability and increased emotional reaction and the impact these changes have had on the patient’s interaction with family, friends, and coworkers. The history includes other stressors and the patient’s ability to cope with stress.

The nurse assesses the patient’s nutritional status and the presence of symptoms. Symptoms related to excessive nervous system output and changes in vision and appearance of the eyes are noted. The nurse periodically assesses and monitors the patient’s cardiac status, including heart rate, blood pressure, heart sounds, and peripheral pulses.

Because emotional changes are associated with hyperthyroidism, the patient’s emotional state and psychological status are evaluated, as are such symptoms as irritability, anxiety, sleep disturbances, apathy, and lethargy, all of which may occur with hyperthyroidism. The family may also provide information about recent changes in the patient’s emotional status.

**Diagnosis**

**NURSING DIAGNOSES**

Based on all the assessment data, the major nursing diagnoses of the patient with hyperthyroidism include the following:

- Imbalanced nutrition, less than body requirements, related to exaggerated metabolic rate, excessive appetite, and increased gastrointestinal activity
- Ineffective coping related to irritability, hyperexcitability, apprehension, and emotional instability
- Low self-esteem related to changes in appearance, excessive appetite, and weight loss
- Altered body temperature
If thyroidectomy is planned, the patient needs to know that pharmacologic therapy is necessary to prepare the thyroid gland for surgical treatment. The nurse instructs and reminds the patient to take the medications as prescribed. Because of hyperexcitability and shortened attention span, the patient may require repetition of this information and written instructions.

**IMPROVING SELF-ESTEEM**

The hyperthyroid patient is likely to experience changes in appearance, appetite, and weight. These factors, along with the patient’s inability to cope well with family and the illness, may result in loss of self-esteem. The nurse conveys an understanding of the patient’s concern about these problems and assists the patient to develop effective coping strategies. The patient and family need to know that these changes are a result of the thyroid dysfunction and are, in fact, out of the patient’s control.

If changes in appearance are very disturbing to the patient, mirrors may be covered or removed. In addition, the nurse reminds family members and personnel to avoid bringing these changes to the patient’s attention. The nurse explains to the patient and family that most of these changes are expected to disappear with effective treatment.

If the patient experiences eye changes secondary to hyperthyroidism, eye care and protection may become necessary. The patient may need instructions about instillation of eye drops or ointment prescribed to soothe the eyes and protect the exposed cornea.

The patient may be embarrassed by the need to eat large meals. Therefore, the nurse arranges for the patient to eat alone if desired and avoids commenting on the patient’s large dietary intake while making sure that the patient receives sufficient food.

**MAINTAINING NORMAL BODY TEMPERATURE**

The patient with hyperthyroidism frequently finds a normal room temperature too warm because of an exaggerated metabolic rate and increased heat production. The nurse maintains the environment at a cool, comfortable temperature and changes bedding and clothing as needed. Cool baths and cool or cold fluids may provide relief. The reason for the patient’s discomfort and the importance of providing a cool environment are explained to the family and staff.

**MONITORING AND MANAGING POTENTIAL COMPLICATIONS**

The nurse closely monitors the patient with hyperthyroidism for signs and symptoms that may be indicative of thyroid storm. Cardiac and respiratory function are assessed by measuring vital signs and cardiac output, ECG monitoring, arterial blood gases, and pulse oximetry. Assessment continues when treatment is initiated because of the potential side effects on cardiac function. Oxygen is administered to prevent hypoxia, to improve tissue oxygenation, and to meet the high metabolic demands. Intravenous fluids may be necessary to maintain blood glucose levels and to replace lost fluids. Antithyroid medications (PTU or methimazole) may be prescribed to reduce thyroid hormone levels. In addition, propranolol and digitalis may be prescribed to treat cardiac symptoms. If shock develops, treatment strategies must be implemented (see Chap. 15).

Hypothyroidism is likely to occur with any of the treatments used to treat hyperthyroidism. Therefore, the nurse periodically monitors the patient. Most patients report a greatly improved sense of well-being after treatment of hyperthyroidism, and some fail to continue to take prescribed thyroid replacement therapy. Therefore, part of patient and family teaching is instruction about the importance of continuing therapy indefinitely after discharge and a discussion of the consequences of failing to take medication.

**PROMOTING HOME AND COMMUNITY-BASED CARE**

**Teaching Patients Self-Care**

The nurse teaches the patient with hyperthyroidism how and when to take prescribed medication, and provides instruction about the essential role of the medication in the broader therapeutic plan. Because of the hyperexcitability and decreased attention span associated with hyperthyroidism, the nurse provides a written plan for the patient to use at home. The type and amount of information given depend on the patient’s stress and anxiety levels. The patient and family members receive verbal and written information about the actions and possible side effects of the medications. The nurse identifies adverse effects that should be reported if they occur (Chart 42-5).

If a total or subtotal thyroidectomy is anticipated, the patient needs information about what to expect. This information is repeated as the time of surgery approaches. The nurse also advises

the patient to avoid stressful situations that may precipitate thyroid storm.

**Continuing Care**

Referral for home care, if indicated, allows the home care nurse to assess the home and family environment and the patient’s and family’s understanding of the importance of adhering to the therapeutic regimen and the recommended follow-up monitoring. The nurse reinforces to the patient and family the importance of long-term follow-up because of the risk for hypothyroidism after thyroidectomy or treatment with antithyroid medications or radioactive iodine. The nurse also assesses the patient for changes indicating return to normal thyroid function and signs and symptoms of hyperthyroidism and hypothyroidism. Further, the nurse reminds the patient and family about the importance of health promotion activities and recommended health screening.

**Evaluation**

**EXPECTED PATIENT OUTCOMES**

Expected patient outcomes may include:

1. Improves nutritional status
   - a. Reports adequate dietary intake and decreased hunger
   - b. Identifies high-calorie, high-protein foods; identifies foods to be avoided
   - c. Avoids use of alcohol and other stimulants
   - d. Reports decreased episodes of diarrhea
2. Demonstrates effective coping methods in dealing with family, friends, and coworkers
   - a. Explains reasons for irritability and emotional instability
   - b. Avoids stressful situations, events, and people
   - c. Participates in relaxing, nonstressful activities
3. Achieves increased self-esteem
   - a. Verbalizes feelings about self and illness
   - b. Describes feelings of frustration and loss of control to others
   - c. Describes reasons for increased appetite
4. Maintains normal body temperature
5. Absence of complications
   - a. Serum thyroid hormone and TSH levels are within normal limits
   - b. Identifies signs and symptoms of thyroid storm and hypothyroidism
   - c. Vital signs and results of ECG, arterial blood gases, and pulse oximetry are within normal limits
   - d. States importance of regular follow-up and lifelong maintenance of prescribed therapy

**THYROIDITIS**

**Thyroiditis,** inflammation of the thyroid gland, can be acute, subacute, or chronic. Each type of thyroiditis is characterized by inflammation, fibrosis, or lymphocytic infiltration of the thyroid gland.

**ACUTE THYROIDITIS**

Acute thyroiditis is a rare disorder caused by infection of the thyroid gland by bacteria, fungi, mycobacteria, or parasites. *Staphylococcus aureus* and other staphylococci are the most common causes. Infection typically causes anterior neck pain and swelling, fever, dysphagia, and dysphonia. Pharyngitis or pharyngeal pain is often present. Examination may reveal warmth, erythema (redness), and tenderness of the thyroid gland. Treatment of acute thyroiditis includes antimicrobial agents and fluid replacement. Surgical incision and drainage may be needed if an abscess is present.

**SUBACUTE THYROIDITIS**

Subacute thyroiditis may be subacute granulomatous thyroiditis (deQuervain’s thyroiditis) or painless thyroiditis (silent thyroiditis or subacute lymphocytic thyroiditis). Subacute granulomatous thyroiditis is an inflammatory disorder of the thyroid gland that predominantly affects women between 40 and 50 years old (Smallridge, 2000). The condition presents as a painful swelling in the anterior neck that lasts 1 to 2 months and then disappears spontaneously without residual effect. It often follows a respiratory infection. The thyroid enlarges symmetrically and may be painful. The overlying skin is often reddened and warm. Swallowing may be difficult and uncomfortable. Irritability, nervousness, insomnia, and weight loss—manifestations of hyperthyroidism—are common, and many patients experience chills and fever as well.

Treatment aims to control the inflammation. In general, non-steroidal anti-inflammatory drugs (NSAIDs) are used to relieve neck pain. Acetylsalicylic acid (aspirin) is avoided if symptoms of hyperthyroidism occur because aspirin displaces thyroid hormone from its binding sites and increases the amount of circulating hormone. Beta-blocking agents (eg, propranolol [Inderal]) may be used to control symptoms of hyperthyroidism. Antithyroid agents, which block the synthesis of T<sub>3</sub> and T<sub>4</sub>, are not effective in thyroiditis because the associated thyrotoxicosis results from the release of stored thyroid hormones rather than from their increased synthesis. In more severe cases, oral corticosteroids may be prescribed to reduce swelling and relieve pain; however, they do not usually affect the underlying cause. In some cases, temporary hypothyroidism may develop and may necessitate thyroid hormone therapy. Follow-up monitoring is necessary to document the patient’s return to a euthyroid state.

Painless thyroiditis (subacute lymphocytic thyroiditis) often occurs in the postpartum period and is thought to be an autoimmune process. Symptoms of hyperthyroidism or hypothyroidism are possible. Treatment is directed at symptoms, and yearly follow-up is recommended to determine the patient’s need for treatment of subsequent hypothyroidism.

**CHRONIC THYROIDITIS (HASHIMOTO’S DISEASE)**

Chronic thyroiditis, which occurs most frequently in women between 30 and 50 years old, has been termed Hashimoto’s disease, or chronic lymphocytic thyroiditis; its diagnosis is based on the histologic appearance of the inflamed gland. In contrast to acute thyroiditis, the chronic forms are usually not accompanied by pain, pressure symptoms, or fever, and thyroid activity is usually normal or low rather than increased. Cell-mediated immunity may play a significant role in the pathogenesis of chronic thyroiditis, and there may be a genetic predisposition to it. If untreated, the disease runs a slow, progressive course, leading eventually to hypothyroidism.

The objective of treatment is to reduce the size of the thyroid gland and prevent hypothyroidism. Thyroid hormone therapy is prescribed to reduce thyroid activity and the production of thyroglobulin. If hypothyroid symptoms are present, thyroid hormone therapy is prescribed. Surgery may be required if pressure symptoms persist.

**THYROID TUMORS**

Tumors of the thyroid gland are classified on the basis of being benign or malignant, the presence or absence of associated thyrotoxicosis, and the diffuse or irregular quality of the glandular...
Some examples of metabolic and endocrine disorders influenced by genetic factors include the following:
- Alpha-1 antitrypsin deficiency
- Cystic fibrosis
- Diabetes mellitus type 1 and type 2
- Hereditary hemochromatosis
- Multiple endocrine neoplasia (MEN) type I and type II
- Von Hippel-Lindau syndrome
- Possibly, the chronic thyroiditis known as Hashimoto’s disease

**NURSING ASSESSMENTS**

**FAMILY HISTORY ASSESSMENT**
- Assess family history for relatives with early-onset hepatic, pancreatic, endocrine disease.
- Inquire about family members with diabetes and their ages at onset.
- Assess family history of other related genetic conditions such as cystic fibrosis, alpha-1 antitrypsin deficiency, hereditary hemochromatosis.

**PHYSICAL ASSESSMENT**
- Assess for physical symptoms such as mucosal neuromas, hypertrophied lips, skeletal abnormalities, and marfanoid appearance.
- Assess for signs of arthritis, bronze pigmentation of the skin (hereditary hemochromatosis).

**MANAGEMENT ISSUES SPECIFIC TO GENETICS**
- Inquire whether DNA mutation testing has been performed on any affected family member.
- If indicated, refer for further genetic counseling and evaluation so that family members can discuss inheritance, risk to other family members, availability of genetic testing and gene-based interventions.
- Offer appropriate genetics information and resources.
- Assess patient’s understanding of genetics information.
- Provide support to families with newly diagnosed genetic-related metabolic and endocrine conditions.
- Participate in management and coordination of care of patients with genetic conditions, individuals predisposed to develop or pass on a genetic condition.

**GENETICS RESOURCES FOR NURSES AND THEIR PATIENTS ON THE WEB**
- Genetic Alliance: [http://www.genet icalliance.org](http://www.genet icalliance.org)—a directory of support groups for patients and families with genetic conditions

- National Organization of Rare Disorders: [http://www.rare-d iseases.org](http://www.rare-d iseases.org)—a directory of support groups and information for patients and families with rare genetic disorders

**ENDEMIC (IODINE-DEFICIENT) GOITER**

The most common type of goiter, encountered chiefly in geographic regions where the natural supply of iodine is deficient (eg, the Great Lakes areas of the United States), is the so-called simple or colloid goiter. In addition to being caused by an iodine deficiency, simple goiter may be caused by an intake of large quantities of goitrogenic substances in patients with unusually susceptible glands. These substances include excessive amounts of iodine or lithium, which is used in treating bipolar disorders.

Simple goiter represents a compensatory hypertrophy of the thyroid gland, caused by stimulation of the pituitary gland. The pituitary gland produces thyrotropin or TSH, a hormone that controls the release of thyroid hormone from the thyroid gland. Its production increases if there is subnormal thyroid activity, as when insufficient iodine is available for production of the thyroid hormone. Such goiters usually cause no symptoms, except for the swelling in the neck, which may result in tracheal compression when excessive.

Many goiters of this type recede after iodine imbalance is corrected. Supplementary iodine, such as SSKI, is prescribed to suppress the pituitary’s thyroid-stimulating activity. When surgery is recommended, the risk for postoperative complications is minimized by ensuring a preoperative euthyroid state by treatment with antithyroid medications and iodide to reduce the size and vascularity of the goiter.

Providing children in iodine-poor regions with iodine compounds can prevent simple or endemic goiter. If the mean iodine intake is less than 40 μg/day, the thyroid gland hypertrophies. The World Health Organization recommends that salt be iodized to a concentration of 1 part in 100,000, which is adequate for the prevention of endemic goiter. In the United States, salt is iodized to 1 part in 10,000. The introduction of iodized salt has been the single most effective means of preventing goiter in at-risk populations.

**NODULAR GOITER**

Some thyroid glands are nodular because of areas of hyperplasia (overgrowth). No symptoms may arise as a result of this condition, but not uncommonly these nodules slowly increase in size, with some descending into the thorax, where they cause local pressure symptoms. Some nodules become malignant, and some
are associated with a hyperthyroid state. Thus, the patient with many thyroid nodules may eventually require surgery.

**THYROID CANCER**

Cancer of the thyroid is much less prevalent than other forms of cancer; however, it accounts for 90% of endocrine malignancies. According to the American Cancer Society (2002), about 20,700 new cases of thyroid cancer are diagnosed each year. Women account for 15,800 of the new cases and men 4,900. About 800 women and 500 men die annually from this malignancy. There are several types of cancer of the thyroid gland; the type determines the course and prognosis (Table 42-3).

External radiation of the head, neck, or chest in infancy and childhood increases the risk of thyroid carcinoma. Between 1940 and 1960, radiation therapy was occasionally used to shrink enlarged tonsillar and adenoid tissue, to treat acne, or to reduce an enlarged thymus. For people exposed to external radiation in childhood, there appears to be an increased incidence of thyroid cancer 5 to 40 years after irradiation. Consequently, people who underwent such treatment should consult a physician, request an isotope thyroid scan as part of the evaluation, follow recommended treatment of abnormalities of the gland, and continue with annual checkups (Chart 42-6).

**Assessment and Diagnostic Findings**

Lesions that are single, hard, and fixed on palpation or associated with cervical lymphadenopathy suggest malignancy. Thyroid function tests may be helpful in evaluating thyroid nodules and masses; however, their results are rarely conclusive. Needle biopsy of the thyroid gland is used as an outpatient procedure to make a diagnosis of thyroid cancer, to differentiate cancerous thyroid nodules from noncancerous nodules, and to stage the cancer if detected. The procedure is safe and usually requires only a local anesthetic. Patients who undergo the procedure are followed closely, however, because cancerous tissues may be missed during the procedure. A second type of aspiration or biopsy uses a large-bore needle rather than the fine needle used in standard biopsy; it may be used when the results of the standard biopsy are inconclusive, or with rapidly growing tumors. Additional diagnostic studies include ultrasound, MRI, CT scans, thyroid scans, radioactive iodine uptake studies, and thyroid suppression tests.

**Medical Management**

The treatment of choice for thyroid carcinoma is surgical removal. Total or near-total thyroidectomy is performed when possible. Modified neck dissection or more extensive radical neck dissection is performed if there is lymph node involvement.

**SURGICAL MANAGEMENT**

Efforts are made to spare parathyroid tissue to reduce the risk for postoperative hypocalcemia and tetany. After surgery, ablation procedures are carried out with radioactive iodine to eradicate residual thyroid tissue if the tumor is radiosensitive. Radioactive iodine also maximizes the chance of discovering thyroid metastasis at a later date if total-body scans are carried out.

After surgery, thyroid hormone is administered in suppressive doses to lower the levels of TSH to a euthyroid state (Thyroid

Patients whose thyroid cancer is detected early and who are appropriately treated usually do very well. Patients who have had papillary cancer, the most common and least aggressive tumor, have a 10-year survival rate greater than 90%. Long-term survival is also common in follicular cancer, a more aggressive form of thyroid cancer (Tierney et al., 2001). Continued thyroid hormone therapy and periodic follow-up and diagnostic testing, however, are important to ensure the patient’s well-being (Thyroid Carcinoma Guidelines, 2001).

Postoperatively, the patient is instructed to take exogenous thyroid hormone to prevent hypothyroidism. Later follow-up includes clinical assessment for recurrence of nodules or masses in the neck and signs of hoarseness, dysphagia, or dyspnea. Total-body scans are performed 2 to 4 months after surgery to detect residual thyroid tissue or metastatic disease. Thyroid hormones are stopped for about 6 weeks before the tests. Care must be taken to avoid iodine-containing foods and contrast agents. A repeat scan is done 1 year after the initial surgery. If measurements are stable, a final scan is obtained in 3 to 5 years.

**FT₄, TSH, serum calcium, and phosphorus levels are monitored to determine whether the thyroid hormone supplementation is adequate and to note whether calcium balance is maintained.**

Although local and systemic reactions to radiation may occur and may include neutropenia or thrombocytopenia, these complications are rare when radioactive iodine is used. Patients who undergo surgery that is combined with radioiodine have a higher survival rate than those undergoing surgery alone. Patient teaching emphasizes the importance of taking prescribed medications and following recommendations for follow-up monitoring. The patient who is undergoing radiation therapy is also instructed in how to assess and manage side effects of treatment.

Partial or complete *thyroidectomy* may be carried out as primary treatment of thyroid carcinoma, hyperthyroidism, or hyperparathyroidism. The type and extent of the surgery depend on the

---

### Chart 42-6 Radiation-Induced Thyroid Damage and Cancer

- The thyroid gland has a very efficient mechanism to remove iodine from the bloodstream and concentrate or "trap" it for subsequent synthesis of thyroid hormone. The effectiveness of this mechanism to concentrate iodide is reflected in a concentration of iodide 20 to 40 times the concentration of iodide in the plasma.
- If milk and other food sources become contaminated with radioactivity as a result of a nuclear detonation or a nuclear power plant incident or mishap, the radioactive iodine would become concentrated in the thyroid gland at a very high concentration and would irradiate the thyroid gland, increasing the risk for thyroid gland cancer. Therefore, in communities exposed to increased radioactivity, attempts have been made to block the uptake of radioactive iodide by flooding or saturating the thyroid gland with nonradioactive iodide.
- Administration of potassium iodide (KI) or other iodide preparations as soon as possible after exposure almost completely inhibits thyroid absorption of the radioactive iodide and promotes rapid excretion of any that is absorbed. In 2001, the Food and Drug Administration (FDA) issued a statement recommending KI administration in advance of exposure to radioactive iodine—that is, when exposure is imminent (FDA, 2001).

---

### Nursing Research Profile 42-1

#### Thyroid Cancer: Patients’ Experiences

**Purpose**

Examination of quality of life and patient experiences for prevalent cancers is well documented in the literature. However, for cancers with low incidence rates, such as thyroid cancer, little information exists. This study examines the experiences of patients who received **¹³¹**I treatment for thyroid cancer. It explores the patients’ perspective of educational needs related to treatment.

**Study Sample and Design**

Patients who had received **¹³¹**I therapy treatment within the previous 2 years were recruited from an oncology/acute care medical unit in a large tertiary medical center. Unstructured focus groups, telephone interviews, and field notes were used in data collection. Five men and 22 women ages 18 to 80 years (mean 38) were asked to respond to an open-ended prompt, such as, “Tell me about your experiences when you were a patient on our unit.” Tape recordings were made during each contact and transcribed verbatim. Thematic analysis was used to identify emerging themes.

**Findings**

Four major themes were elicited from the analysis: recognizing the totality of the cancer experience, recognizing the totality of the treatment experiences, being isolated, and understanding barriers to treatment. Participants reported that health care providers did not understand the totality of their experience and that the experiences were often unrecognized or minimized. Isolation left many participants feeling uncared for and ignored. Effective communication by health care providers was identified as an important part of the support needed by patients. Information provided by caregivers was inconsistent, leaving the patients feeling confused and concerned that nurses and other care providers were unaware of the implications of receiving **¹³¹**I therapy.

**Nursing Implications**

Patients receiving **¹³¹**I therapy share many of the fears and concerns expressed by those receiving treatment for more prevalent forms of cancer. Effective communication is an essential component in addressing the psychosocial and physical needs of these patients. Comprehensive education programs for staff and patients prior to therapy are critical in providing consistent quality care. These programs must address the fears resulting from a lack of understanding and the implications associated with **¹³¹**I therapy treatment to address the totality of the experience.
diagnosis, goal of surgery, and prognosis. Thyroidectomy may be the treatment of choice for patients with symptomatic hyperparathyroidism (see later discussion), kidney stones, or bone disease.

The patient undergoing surgery for treatment of hyperthyroidism is given appropriate medications to return the thyroid hormone levels and metabolic rate to normal and to reduce the risk for thyroid storm and hemorrhage during the postoperative period. Medications that may prolong clotting (eg, aspirin) are stopped several weeks before surgery to minimize the risk for postoperative bleeding.

Nursing Management

Important preoperative goals are to gain the patient’s confidence and reduce anxiety. Often, the patient’s home life has become tense because of his or her restlessness, irritability, and nervousness secondary to hyperthyroidism. Efforts are necessary to protect the patient from such tension and stress to avoid precipitating thyroid storm. If the patient reports increased stress when with family or friends, suggestions are made to limit contact with them. Quiet and relaxing forms of recreation or occupational therapy may be helpful.

PROVIDING PREOPERATIVE CARE

The nurse instructs the patient about the importance of eating a diet high in carbohydrates and proteins. A high daily caloric intake is necessary because of the increased metabolic activity and rapid depletion of glycogen reserves. Supplementary vitamins, particularly thiamine and ascorbic acid, may be prescribed. The patient is reminded to avoid tea, coffee, cola, and other stimulants.

The nurse also informs the patient about the purpose of preoperative tests, if they are to be performed, and explains what preoperative preparations to expect. The information should help to reduce the patient’s anxiety about the surgery. In addition, special efforts are made to ensure a good night’s rest before surgery, although many patients are admitted to the hospital on the day of surgery.

Preoperative teaching includes demonstrating to the patient how to support the neck with the hands after surgery to prevent strain and tension on the neck muscles and the surgical incision.

PROVIDING POSTOPERATIVE CARE

The nurse periodically assesses the surgical dressings and reinforces them when necessary. When the patient is in a recumbent position, the nurse observes the sides and the back of the neck as well as the anterior dressing for bleeding. In addition to monitoring the pulse and blood pressure for any indication of internal bleeding, it is also important to be alert for complaints of a sensation of pressure or fullness at the incision site. Such symptoms may indicate hemorrhage and hematoma formation subcutaneously and should be reported.

Difficulty in respiration occurs as a result of edema of the glottis, hematoma formation, or injury to the recurrent laryngeal nerve. This complication requires that an airway be inserted. Therefore, a tracheostomy is performed. The airway is inserted when necessary. The patient is usually permitted out of bed as soon as possible and is encouraged to eat foods that are easily eaten. A well-balanced, high-calorie diet may be prescribed to promote weight gain. Sutures or skin clips are usually removed on the second day. The patient is usually discharged from the hospital the day of surgery or soon afterward if the postoperative course is uncomplicated.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Hemorrhage, hematoma formation, edema of the glottis, and injury to the recurrent laryngeal nerve are complications that have been reviewed previously in this chapter. Occasionally in thyroid surgery the parathyroid glands are injured or removed, producing a disturbance in calcium metabolism. As the blood calcium level falls, hyperirritability of the nerves occurs, with spasms of the hands and feet and muscle twitching. This group of symptoms is termed tetany, and the nurse must immediately report its appearance because laryngospasm, although rare, may occur and obstruct the airway. Tetany of this type is usually treated with intravenous calcium gluconate. This calcium abnormality is usually temporary after thyroidectomy.

PROMOTING HOME AND COMMUNITY-BASED CARE

Teaching Patients Self-Care. The patient may be discharged the evening of surgery or within 1 to 2 days. Therefore, the patient and family need to be knowledgeable about the signs and symptoms of the complications that may occur and those that should be reported. Strategies are suggested for managing postoperative pain at home and for increasing humidification. The nurse explains to the patient and family the need for rest, relaxation, and nutrition. The patient is permitted to resume his or her former activities and responsibilities completely once recovered from surgery.

Continuing Care. If indicated, a referral to home care is made. The home care nurse assesses the patient’s recovery from surgery. The nurse also assesses the surgical incision and reinforces instruction about limiting activities that put strain on the incision and sutures. Family responsibilities and factors relating to the home environment that produce emotional tension have often been implicated as precipitating causes of thyrotoxicosis. A home visit provides an opportunity to evaluate these factors and to suggest ways to improve the home and family environment. The nurse gives specific instructions regarding follow-up visits to the
physician or the clinic, which are important for monitoring the thyroid status.

Management of Patients With Parathyroid Disorders

The parathyroid glands (normally four) are situated in the neck and embedded in the posterior aspect of the thyroid gland (Fig. 42-5). These small glands are easily overlooked and can be removed inadvertently during thyroid surgery. Inadvertent surgical removal is the most common cause of hypoparathyroidism.

PARATHYROID FUNCTION

Parathormone, the protein hormone from the parathyroid glands, regulates calcium and phosphorus metabolism. Increased secretion of parathormone results in increased calcium absorption from the kidney, intestine, and bones, thereby raising the blood calcium level. Some actions of this hormone are increased by the presence of vitamin D. Parathormone also tends to lower the blood phosphorus level.

Excess parathormone can result in markedly elevated levels of serum calcium, a potentially life-threatening situation. When the product of serum calcium and serum phosphorus (calcium × phosphorus) rises, calcium phosphate may precipitate in various organs of the body and cause tissue calcification.

The serum level of ionized calcium regulates the output of parathormone. Increased serum calcium results in decreased parathormone secretion, creating a negative feedback system.

HYPERPARATHYROIDISM

Hyperparathyroidism, which is caused by overproduction of parathyroid hormone by the parathyroid glands, is characterized by bone decalcification and the development of renal calculi (kidney stones) containing calcium.

Primary hyperparathyroidism occurs two to four times more often in women than in men and is most common in patients between 60 and 70 years of age. About 100,000 new cases of hyperparathyroidism are detected each year in the United States. The disease is rare in children younger than 15 years, but the incidence increases tenfold between the ages of 15 and 65 years. Half of the patients diagnosed with hyperparathyroidism do not have symptoms.

Secondary hyperparathyroidism, with manifestations similar to those of primary hyperparathyroidism, occurs in patients with chronic renal failure and so-called renal rickets as a result of phosphorus retention, increased stimulation of the parathyroid glands, and increased parathyroid hormone secretion.

Clinical Manifestations

The patient may have no symptoms or may experience signs and symptoms resulting from involvement of several body systems. Apathy, fatigue, muscle weakness, nausea, vomiting, constipation, hypertension, and cardiac dysrhythmias may occur; all are attributable to the increased concentration of calcium in the blood. Psychological manifestations may vary from irritability and neurosis to psychoses caused by the direct effect of calcium on the brain and nervous system. An increase in calcium produces a decrease in the excitation potential of nerve and muscle tissue.

The formation of stones in one or both kidneys, related to the increased urinary excretion of calcium and phosphorus, is one of the important complications of hyperparathyroidism and occurs in 55% of patients with primary hyperparathyroidism. Renal damage results from the precipitation of calcium phosphate in the renal pelvis and parenchyma, resulting in renal calculi (kidney stones), obstruction, pyelonephritis, and renal failure.

Musculoskeletal symptoms accompanying hyperparathyroidism may result from demineralization of the bones or bone tumors composed of benign giant cells resulting from overgrowth of osteoclasts. The patient may develop skeletal pain and tenderness, especially of the back and joints; pain on weight bearing; pathologic fractures; deformities; and shortening of body stature. Bone loss attributable to hyperparathyroidism increases the risk for fracture.

The incidence of peptic ulcer and pancreatitis is increased with hyperparathyroidism and may be responsible for many of the gastrointestinal symptoms that occur.

Assessment and Diagnostic Findings

Primary hyperparathyroidism is diagnosed by persistent elevation of serum calcium levels and an elevated level of parathormone. Radioimmunoassays for parathormone are sensitive and differentiate primary hyperparathyroidism from other causes of hypercalcemia in more than 90% of patients with elevated serum calcium levels. An elevated serum calcium level alone is a nonspecific finding because serum levels may be altered by diet, medications, and renal and bone changes. Bone changes may be detected on x-ray or bone scans in advanced disease. The double antibody parathyroid hormone test is used to distinguish between primary hyperparathyroidism and malignancy as a cause of hypercalcemia. Ultrasound, MRI, thallium scan, and fine-needle biopsy have been used to evaluate the function of the parathyroids and to localize parathyroid cysts, adenomas, or hyperplasia.
Complications: Hypercalcemic Crisis

Acute hypercalcemic crisis can occur with extreme elevation of serum calcium levels. Serum calcium levels higher than 15 mg/dL (3.7 mmol/L) result in neurologic, cardiovascular, and renal symptoms that can be life-threatening. Treatment includes hydration with large volumes of intravenous fluids, diuretic agents to promote renal excretion of excess calcium, and phosphate therapy to correct hypophosphatemia and decrease serum calcium levels by promoting calcium deposit in bone and reducing the gastrointestinal absorption of calcium. Cytotoxic agents (mithramycin), calcitonin, and dialysis may be used in emergency situations to decrease serum calcium levels quickly.

A combination of calcitonin and corticosteroids has been administered in emergencies to reduce the serum calcium level by increasing calcium deposition in bone. Other agents that may be administered to decrease serum calcium levels include bisphosphonates (e.g., etidronate [Didronel], pamidronate).

The patient requires expert assessment and care to minimize complications and reverse the life-threatening hypercalcemia. Medications are administered with care, and attention is given to fluid balance to promote return of normal fluid and electrolyte balance. Supportive measures are necessary for the patient and family.

Medical Management

The insidious onset and chronic nature of hyperparathyroidism and its diverse and commonly vague symptoms may result in depression and frustration. The family may have considered the patient’s illness to be psychosomatic. An awareness of the course of the disorder and an understanding approach by the nurse may help the patient and family to deal with their reactions and feelings. The recommended treatment of primary hyperparathyroidism is the surgical removal of abnormal parathyroid tissue. In some patients without symptoms and with only mildly elevated serum calcium levels and normal renal function, surgery may be delayed and the patient followed closely for worsening of hypercalcemia, bone deterioration, renal impairment, or the development of kidney stones.

HYDRATION THERAPY

Because kidney involvement is possible, patients with hyperparathyroidism are at risk for renal calculi. Therefore, a fluid intake of 2,000 mL or more is encouraged to help prevent calculus formation. Cranberry juice is suggested because it may lower the urinary pH. It can be added to juices and ginger ale for variety. The patient is instructed to report other manifestations of renal calculi, such as abdominal pain and hematuria. Thiazide diuretics are avoided because they decrease the renal excretion of calcium and further elevate serum calcium levels. Because of the risk of hypercalcemic crisis, the patient is instructed to avoid dehydration and to seek immediate health care if conditions that commonly produce dehydration (e.g., vomiting, diarrhea) occur.

MOBILITY

Mobility of the patient, with walking or use of a rocking chair for those with limited mobility, is encouraged as much as possible because bones subjected to normal stress give up less calcium. Bed rest increases calcium excretion and the risk for renal calculi. Oral phosphates lower the serum calcium level in some patients. Long-term use is not recommended because of the risk for ectopic calcium phosphate deposits in soft tissues.

DIET AND MEDICATIONS

Nutritional needs are met, but the patient is advised to avoid a diet with restricted or excess calcium. If the patient has a coexisting peptic ulcer, prescribed antacids and protein feedings are necessary. Because anorexia is common, efforts are made to improve the appetite. Prune juice, stool softeners, and physical activity, along with increased fluid intake, help to offset constipation, which is common postoperatively.

Nursing Management

The nursing management of the patient undergoing parathyroidectomy is essentially the same as that of a patient undergoing thyroidectomy. However, the previously described precautions about dehydration, immobility, and diet are particularly important in the patient awaiting and recovering from parathyroidectomy. Although not all parathyroid tissue is removed during surgery in an effort to control the calcium–phosphorus balance, the nurse closely monitors the patient to detect symptoms of tetany (which may be an early postoperative complication). Most patients quickly regain function of the remaining parathyroid tissue and experience only mild, transient postoperative hypocalcemia. In patients with significant bone disease or bone changes, a more prolonged period of hypocalcemia should be anticipated. The nurse reminds the patient and family about the importance of follow-up to ensure return of serum calcium levels to normal (Chart 42-7).

HYPOPARATHYROIDISM

The most common cause of hypoparathyroidism is inadequate secretion of parathyroid hormone after interruption of the blood supply or surgical removal of parathyroid gland tissue during thyroidectomy, parathyroidectomy, or radical neck dissection. Atrophy of the parathyroid glands of unknown cause is a less common cause of hypoparathyroidism.

Pathophysiology

Symptoms of hypoparathyroidism are caused by a deficiency of parathormone that results in elevated blood phosphate (hyperphosphatemia) and decreased blood calcium (hypocalcemia) levels. In the absence of parathormone, there is decreased intestinal absorption of dietary calcium and decreased resorption of calcium from bone and through the renal tubules. Decreased renal excretion of phosphate causes hypophosphaturia, and low serum calcium levels result in hypocalciuria.

Clinical Manifestations

Hypocalcemia causes irritability of the neuromuscular system and contributes to the chief symptom of hypoparathyroidism—tetany. Tetany is a general muscle hypertonia, with tremor and spasmatic or uncoordinated contractions occurring with or without efforts to make voluntary movements. Symptoms of latent tetany are numbness, tingling, and cramps in the extremities, and the patient complains of stiffness in the hands and feet. In overt tetany, the
signs include bronchospasm, laryngeal spasm, carpopedal spasm (flexion of the elbows and wrists and extension of the carpophalangeal joints), dysphagia, photophobia, cardiac dysrhythmias, and seizures. Other symptoms include anxiety, irritability, depression, and even delirium. ECG changes and hypotension also may occur.

Assessment and Diagnostic Findings

A positive Trousseau’s sign or a positive Chvostek’s sign suggests latent tetany. Trousseau’s sign is positive when carpopedal spasm is induced by occluding the blood flow to the arm for 3 minutes with a blood pressure cuff. Chvostek’s sign is positive when a sharp tapping over the facial nerve just in front of the parotid gland and anterior to the ear causes spasm or twitching of the mouth, nose, and eye (see Chap. 14).

The diagnosis of hypoparathyroidism often is difficult because of the vague symptoms, such as aches and pains. Therefore, laboratory studies are especially helpful. Tetany develops at serum calcium levels of 5 to 6 mg/dL (1.2 to 1.5 mmol/L) or lower. Serum phosphate levels are increased, and x-rays of bone show increased density. Calcification is detected on x-rays of the subcutaneous or paraspinal basal ganglia of the brain.

Medical Management

The goal of therapy is to raise the serum calcium level to 9 to 10 mg/dL (2.2 to 2.5 mmol/L) and to eliminate the symptoms of hypoparathyroidism and hypocalcemia. When hypocalcemia and tetany occur after a thyroidectomy, the immediate treatment is to administer calcium gluconate intravenously. If this does not decrease neuromuscular irritability and seizure activity immediately, sedative agents such as pentobarbital may be administered.

Parenteral parathormone can be administered to treat acute hypoparathyroidism with tetany. The high incidence of allergic reactions to injections of parathormone, however, limits its use to acute episodes of hypocalcemia. The patient receiving parathormone is monitored closely for allergic reactions and changes in serum calcium levels.

Because of neuromuscular irritability, the patient with hypocalcemia and tetany requires an environment that is free of noise, drafts, bright lights, or sudden movement. Tracheostomy or mechanical ventilation may become necessary, along with bronchodilating medications, if the patient develops respiratory distress.

Therapy for the patient with chronic hypoparathyroidism is determined after serum calcium levels are obtained. A diet high in calcium and low in phosphorus is prescribed. Although milk, milk products, and egg yolk are high in calcium, they are restricted because they also contain high levels of phosphorus. Spinach also is avoided because it contains oxalate, which would form insoluble calcium substances. Oral tablets of calcium salts, such as calcium gluconate, may be used to supplement the diet. Aluminum hydroxide gel or aluminum carbonate (Gelusil, Amphojel) also is administered after meals to bind phosphate and promote its excretion through the gastrointestinal tract.

Variable dosages of a vitamin D preparation—dihydrotachysterol (AT 10 or Hytakerol), ergocalciferol (vitamin D), cholecalciferol (vitamin D)—are usually required and enhance calcium absorption from the gastrointestinal tract.

Nursing Management

Nursing management of the patient with possible acute hypoparathyroidism includes the following:

- Care of postoperative patients having thyroidectomy, parathyroidectomy, and radical neck dissection is directed toward detecting early signs of hypocalcemia and anticipating signs of tetany, seizures, and respiratory difficulties.
- Calcium gluconate is kept at the bedside, with equipment necessary for intravenous administration. If the patient has a cardiac disorder, is subject to dysrhythmias, or is receiving digitalis, calcium gluconate is administered slowly and cautiously.
- Calcium and digitalis increase systolic contraction and also potentiate each other; this may produce potentially fatal dysrhythmias. Consequently, the cardiac patient requires continuous cardiac monitoring and careful assessment.

An important aspect of nursing care is teaching about medications and diet therapy. The patient needs to know the reason for high calcium and low phosphate intake and the symptoms of hypocalcemia and hypercalcemia; he or she should know to

Management of Patients With Adrenal Disorders

There are two adrenal glands in the human, each attached to the upper portion of a kidney. Each adrenal gland is, in reality, two endocrine glands with separate, independent functions. The adrenal medulla at the center of the gland secretes catecholamines, and the outer portion of the gland, the adrenal cortex, secretes steroid hormones (Fig. 42-6). The secretion of hormones from the adrenal cortex is regulated by the hypothalamic-pituitary-adrenal axis. The hypothalamus secretes corticotropin-releasing hormone (CRH), which in turn stimulates the pituitary gland to secrete ACTH. ACTH then stimulates the adrenal cortex to secrete glucocorticoid hormone (cortisol). Increased levels of the adrenal hormone then inhibit the production or secretion of CRH and ACTH. This system is an example of a negative feedback mechanism.

ADRENAL FUNCTION

Adrenal Medulla

The adrenal medulla functions as part of the autonomic nervous system. Stimulation of preganglionic sympathetic nerve fibers, which travel directly to the cells of the adrenal medulla, causes release of the catecholamine hormones epinephrine and norepinephrine. About 90% of the secretion of the human adrenal medulla is epinephrine (also called adrenaline). Catecholamines regulate metabolic pathways to promote catabolism of stored fuels to meet caloric needs from endogenous sources. The major effects of epinephrine release are to prepare to meet a challenge (fight-or-flight response). Secretion of epinephrine causes decreased blood flow to tissues that are not needed in emergency situations, such as the gastrointestinal tract, and causes increased...

**Home Care Checklist – The Patient With Hypoparathyroidism**

At the completion of the home care instruction, the patient or caregiver will be able to:

- State present and potential effects of hypoparathyroidism on the body
- State precipitating factors and interventions for complications (seizure, cardiac dysrhythmias, cardiac arrest)
- State necessary actions for seizure activity
- State importance of regular follow-up visits with health care provider
- State purpose, dose, route, schedule, side effects, and precautions of prescribed medications (calcium, phosphate binders)
- State need to alternate activity and rest periods
- Identify areas of activity limitations and impact on lifestyle
- Identify foods high in calcium and vitamin D, low in phosphorus

</table>
blood flow to tissues that are important for effective fight or flight, such as cardiac and skeletal muscle. Catecholamines also induce the release of free fatty acids, increase the basal metabolic rate, and elevate the blood glucose level.

Adrenal Cortex

A functioning adrenal cortex is necessary for life; adenocortical secretions make it possible for the body to adapt to stress of all kinds. The three types of steroid hormones produced by the adrenal cortex are glucocorticoids, the prototype of which is hydrocortisone; mineralocorticoids, mainly aldosterone; and sex hormones, mainly androgens (male sex hormones). Without the adrenal cortex, severe stress would cause peripheral circulatory failure, circulatory shock, and prostration. Survival in the absence of a functioning adrenal cortex is possible only with nutritional, electrolyte, and fluid replacement and appropriate replacement with exogenous adenocortical hormones.

GLUCOCORTICOIDS

The glucocorticoids are so named because they have an important influence on glucose metabolism: increased hydrocortisone secretion results in elevated blood glucose levels. However, the glucocorticoids have major effects on the metabolism of almost all organs of the body. Glucocorticoids are secreted from the adrenal cortex in response to the release of ACTH from the anterior lobe of the pituitary gland. This system represents an example of negative feedback. The presence of glucocorticoids in the blood inhibits the release of corticotropin-releasing factor from the hypothalamus and also inhibits ACTH secretion from the pituitary. The resultant decrease in ACTH secretion causes diminished release of glucocorticoids from the adrenal cortex.

Glucocorticoids (in the form of corticosteroids) are administered frequently to inhibit the inflammatory response to tissue injury and suppress allergic manifestations. Their side effects include the development of diabetes mellitus, osteoporosis, peptic ulcer, increased protein breakdown resulting in muscle wasting and poor wound healing, and redistribution of body fat.

Large amounts of exogenously administered glucocorticoids in the blood inhibit the release of ACTH and endogenous glucocorticoids. Because of this, the adrenal cortex can atrophy. If exogenous glucocorticoid administration is discontinued suddenly, adrenal insufficiency results because of the inability of the atrophied cortex to respond adequately.

MINERALOCORTICOIDS

Mineralocorticoids exert their major effects on electrolyte metabolism. They act principally on the renal tubular and gastrointestinal epithelium to cause increased sodium ion absorption in exchange for excretion of potassium or hydrogen ions. ACTH only minimally influences aldosterone secretion. It is primarily secreted in response to the presence of angiotensin II in the bloodstream. Angiotensin II is a substance that elevates the blood pressure by constricting arterioles. Its concentration is increased when renin is released from the kidney in response to decreased perfusion pressure. The resultant increased aldosterone levels promote sodium reabsorption by the kidney and the gastrointestinal tract, which tends to restore blood pressure to normal. The release of aldosterone is also increased by hyperkalemia. Aldosterone is the primary hormone for the long-term regulation of sodium balance.

ADRENAL SEX HORMONES (ANDROGENS)

Androgens, the third major type of steroid hormones produced by the adrenal cortex, exert effects similar to those of male sex hormones. The adrenal gland may also secrete small amounts of some estrogens, or female sex hormones. ACTH controls the secretion of adrenal androgens. When secreted in normal amounts, the adrenal androgens probably have little effect, but when secreted in excess, in certain inborn enzyme deficiencies, masculinization may result. This is termed the adrenogenital syndrome.

PHEOCHROMOCYTOMA

Pheochromocytoma is a tumor that is usually benign and originates from the chromaffin cells of the adrenal medulla. In 80% to 90% of patients (O’Connell, 1999), the tumor arises in the medulla; in the remaining patients, it occurs in the extra-adrenal chromaffin tissue located in or near the aorta, ovaries, spleen, or other organs. Pheochromocytoma may occur at any age, but its peak incidence is between ages 40 and 50 years (Rakel & Bope, 2001). It affects men and women equally. Because of the high incidence of pheochromocytoma in family members, the patient’s family members should be alerted and screened for this tumor. Ten percent of the tumors are bilateral, and 10% are malignant.

Pheochromocytoma is the cause of high blood pressure in 0.2% of patients with new onset of hypertension (O’Connell, 1999). Although it is uncommon, it is one form of hypertension that is usually cured by surgery; without detection and treatment, it is usually fatal. Pheochromocytoma may occur in the familial form as part of multiple endocrine neoplasia type 2; therefore, it should be considered a possibility in patients with medullary thyroid carcinoma and parathyroid hyperplasia or tumor.

Clinical Manifestations

The nature and severity of symptoms of functioning tumors of the adrenal medulla depend on the relative proportions of epinephrine and norepinephrine secretion. The typical triad of symptoms comprises headache, diaphoresis, and palpitations (Matthews et al., 1999). Hypertension and other cardiovascular disturbances are common. The hypertension may be intermittent or persistent. Only half of patients with pheochromocytoma, however, have sustained or persistent hypertension. If the hypertension is sustained, it may be difficult to distinguish from other causes of hypertension. Other symptoms may include tremor, headache, flushing, and anxiety. Hyperglycemia may result from conversion of liver and muscle glycogen to glucose by epinephrine secretion; insulin may be required to maintain normal blood glucose levels.

The clinical picture in the paroxysmal form of pheochromocytoma is usually characterized by acute, unpredictable attacks lasting seconds or several hours. During these attacks, the patient is extremely anxious, tremulous, and weak. The patient may experience headache, vertigo, blurring of vision, tinnitus, air hunger, and dyspnea. Other symptoms include polyuria, nausea, vomiting, diarrhea, abdominal pain, and a feeling of impending doom. Palpitations and tachycardia are common. Blood pressures exceeding 250/150 mm Hg have been recorded. Such blood pressure elevations are life-threatening and may cause severe complications, such as cardiac dysrhythmias, dissecting aneurysm, stroke, and acute renal failure. Postural hypotension occurs in 70% of patients with untreated pheochromocytoma.

Chapter 42 Assessment and Management of Patients With Endocrine Disorders

PHEOCHROMOCYTOMA
Assessment and Diagnostic Findings

Pheochromocytoma is suspected if signs of sympathetic nervous system overactivity occur in association with marked elevation of blood pressure. These signs can be associated with the “five Hs”: hypertension, headache, hyperhidrosis (excessive sweating), hypermetabolism, and hyperglycemia. The presence of these signs has a 93.8% specificity and a 90.9% sensitivity for pheochromocytoma. Absence of hypertension excludes pheochromocytoma with a 99% certainty. Paroxysmal symptoms of pheochromocytoma commonly develop in the fifth decade of life.

Measurements of urine and plasma levels of catecholamines are the most direct and conclusive tests for overactivity of the adrenal medulla. Measurements of urinary catecholamine metabolites (metanephrines [MN] and vanillylmandelic acid [VMA]) or free catecholamines are the standard diagnostic tests used in the diagnosis of pheochromocytoma. Levels can be as high as three times normal limits (O’Connell, 1999). A 24-hour specimen of urine is collected for determining free catecholamines, MN, and VMA; the use of combined tests increases the diagnostic accuracy of testing. A number of medications and foods (eg, coffee, tea, bananas, chocolate, vanilla, aspirin) may alter the results of these tests; therefore, careful instructions to avoid restricted items must be given to the patient. Urine collected over a 2- or 3-hour period after an attack of hypertension can be assayed for catecholamine content.

Total plasma catecholamine (epinephrine and norepinephrine) concentration is measured with the patient supine and at rest for 30 minutes. To prevent elevation of catecholamine levels by the stress of venipuncture, a butterfly needle, scalp vein needle, or venous catheter may be inserted 30 minutes before the blood specimen is obtained.

Factors that may elevate catecholamine levels must be controlled to obtain valid results; these factors include consumption of coffee or tea, use of tobacco, emotional and physical stress, and use of many prescription and over-the-counter medications (eg, amphetamines, nose drops or sprays, decongestant agents, and bronchodilators).

Normal plasma values of epinephrine are 100 pg/mL (590 pmol/L); normal values of norepinephrine are generally less than 100 to 550 pg/mL (590 to 3,240 pmol/L). Values of epinephrine greater than 400 pg/mL (2,180 pmol/L) or norepinephrine values greater than 2,000 pg/mL (11,800 pmol/L) are considered diagnostic of pheochromocytoma. Values that fall between normal values and those diagnostic of pheochromocytoma indicate the need for further testing.

A clonidine suppression test may be performed if the results of plasma and urine tests of catecholamines are inconclusive. Clonidine (Catapres) is a centrally acting, antiadrenergic medication that suppresses the release of neurogenically mediated catecholamines. The suppression test is based on the principle that clonidine levels are normally increased through the activity of the sympathetic nervous system. In pheochromocytoma, increased catecholamine levels result from the diffusion of excess catecholamines into the circulation, bypassing normal storage and release mechanisms. Therefore, in patients with pheochromocytoma, clonidine does not suppress the release of catecholamines.

The results of the test are considered normal if 2 to 3 hours after a single oral dose of clonidine, the total plasma catecholamine value decreases at least 40% from baseline. Patients with pheochromocytoma exhibit no change in catecholamine levels. False-positive results, however, may occur in patients with primary hypertension.

Imaging studies, such as CT scans, MRI, and ultrasound, may also be carried out to localize the pheochromocytoma and to determine whether more than one tumor is present. Use of 123I-metaiodobenzylguanidine (MIBG) scintigraphy may be required to determine the location of the pheochromocytoma and to detect metastatic sites outside the adrenal gland. MIBG is a specific isotope for catecholamine-producing tissue. It has been helpful in identifying tumors not detected by other tests or procedures. MIBG scintigraphy is a noninvasive, safe procedure that has increased the accuracy of diagnosis of adrenal tumors.

Other diagnostic studies may focus on evaluating the function of other endocrine glands because of the association of pheochromocytoma in some patients with other endocrine tumors.

Medical Management

During an episode or attack of hypertension, tachycardia, anxiety, and the other symptoms of pheochromocytoma, the patient is placed on bed rest with the head of the bed elevated to promote an orthostatic decrease in blood pressure.

PHARMACOLOGIC THERAPY

The patient may be moved to the intensive care unit for close monitoring of ECG changes and careful administration of alpha-adrenergic blocking agents (eg, phentolamine [Regitine]) or smooth muscle relaxants (eg, sodium nitroprusside [Nipride]) to lower the blood pressure quickly.

Phenoxybenzamine (Dibenzyline), a long-acting alpha-blocker, may be used when the blood pressure is stable to prepare the patient for surgery. Beta-adrenergic blocking agents, such as propranolol (Inderal), may be used in patients with cardiac dysrhythmias or those not responsive to alpha-blockers. Alpha-adrenergic and beta-adrenergic blocking agents must be used with caution because patients with pheochromocytoma may have increased sensitivity to them. Still other medications that may be used preoperatively are catecholamine synthesis inhibitors, such as alpha-methyl-p-tyrosine (metryrosine). These are occasionally used when adrenergic blocking agents do not reduce the effects of catecholamines.

SURGICAL MANAGEMENT

The definitive treatment of pheochromocytoma is surgical removal of the tumor, usually with adrenalectomy. Bilateral adrenalectomy may be necessary if tumors are present in both adrenal glands. Patient preparation includes control of blood pressure and blood volumes; usually this is carried out over 7 to 10 days. Phentolamine or phenoxybenzamine (Dibenzyline) may be used safely without causing undue hypotension. Other medications (metryrosine [Demser] and prazosin [Minipress]) have been used to treat pheochromocytoma. The patient needs to be well hydrated before, during, and after surgery to prevent hypotension.

Manipulation of the tumor during surgical excision may cause release of stored epinephrine and norepinephrine, with marked increases in blood pressure and changes in heart rate. Therefore, use of sodium nitroprusside (Nipride) and alpha-adrenergic blocking agents may be required during and after surgery. Exploration of other possible tumor sites is frequently undertaken to ensure removal of all tumor tissue. As a result, the patient is subject to the stress and effects of a long surgical procedure, which may increase the risk of hypertension postoperatively.

Corticosteroid replacement is required if bilateral adrenalectomy has been necessary. Corticosteroids may also be necessary
for the first few days or weeks after removal of a single adrenal gland. Intravenous administration of corticosteroids (methylprednisolone sodium succinate [Solu-Medrol]) may begin the evening before surgery and continue during the early postoperative period to prevent adrenal insufficiency. Oral preparations of corticosteroids (prednisone) will be prescribed after the acute stress of surgery diminishes.

Hypotension and hypoglycemia may occur in the postoperative period because of the sudden withdrawal of excessive amounts of catecholamines. Therefore, careful attention is directed toward monitoring and treating these changes. Blood pressure is expected to return to normal with treatment; however, one third of patients continue to be hypertensive after surgery. This may result if not all pheochromocytoma tissue was removed, if pheochromocytoma recurs, or if the blood vessels were damaged by severe and prolonged hypertension. Several days after surgery, urine and plasma levels of catecholamines and their metabolites are measured to determine whether surgery was successful.

**Nursing Management**

The patient who has undergone surgery to treat pheochromocytoma has experienced a stressful preoperative and postoperative course and may remain fearful of repeated attacks. Although it is usually expected that all pheochromocytoma tissue has been removed, there is a possibility that other sites were undetected and that attacks may recur. The patient is monitored for several days in the intensive care unit with special attention given to ECG changes, arterial pressures, fluid and electrolyte balance, and blood glucose levels. Several intravenous lines are inserted for administration of fluids and medications.

**PROMOTING HOME AND COMMUNITY-BASED CARE**

**Teaching Patients Self-Care.** During the preoperative and postoperative phases of care, the nurse informs the patient about the importance of follow-up monitoring to ensure that pheochromocytoma does not recur undetected. After adrenalectomy, use of corticosteroids may be needed. Therefore, the nurse instructs the patient about their purpose, the medication schedule, and the risks of skipping doses or stopping their administration abruptly.

It is important to teach the patient and family how to measure the patient’s blood pressure and when to notify the physician about changes in blood pressure. Additionally, the nurse provides verbal and written instructions about the procedure for collecting 24-hour urine specimens to monitor urine catecholamine levels.

**Continuing Care.** A follow-up visit from a home care nurse may be indicated to assess the patient’s postoperative recovery, surgical incision, and compliance with the medication schedule. This may help to reinforce previous teaching about management and monitoring. The home care nurse also obtains blood pressure measurements and assists the patient in preventing or dealing with problems that may result from long-term use of corticosteroids.

Because of the risk of recurrence of hypertension, periodic checkups are required, especially in young patients and in patients whose families have a history of pheochromocytoma. The patient is scheduled for periodic follow-up appointments to observe for return of normal blood pressure and plasma and urine levels of catecholamines.

**ADRENOCORTICAL INSUFFICIENCY (ADDISON’S DISEASE)**

**Pathophysiology**

Addison’s disease, or adrenocortical insufficiency, results when adrenal cortex function is inadequate to meet the patient’s need for cortical hormones. Autoimmune or idiopathic atrophy of the adrenal glands is responsible for 80% of cases (Rakel & Bope, 2001). Other causes include surgical removal of both adrenal glands or infection of the adrenal glands. Tuberculosis and histoplasmosis are the most common infections that destroy adrenal gland tissue. Although autoimmune destruction has replaced tuberculosis as the principal cause of Addison’s disease, tuberculosis should be considered in the diagnostic workup because of its increasing incidence. Inadequate secretion from the pituitary gland also results in adrenal insufficiency because of decreased stimulation of the adrenal cortex.

Therapeutic use of corticosteroids is the most common cause of adrenocortical insufficiency (Coursin & Wood, 2002). The symptoms of adrenocortical insufficiency may also result from the sudden cessation of exogenous adrenocortical hormonal therapy, which suppresses the body’s normal response to stress and interferes with normal feedback mechanisms. Treatment with daily administration of corticosteroids for 2 to 4 weeks may suppress function of the adrenal cortex; therefore, adrenal insufficiency should be considered in any patient who has been treated with corticosteroids.

**Clinical Manifestations**

Addison’s disease is characterized by muscle weakness, anorexia, gastrointestinal symptoms, fatigue, emaciation, dark pigmentation of the skin, knuckles, knees, elbows, and mucous membranes, hypotension, and low blood glucose levels, low serum sodium levels, and high serum potassium levels. Mental status changes such as depression, emotional lability, apathy, and confusion are present in 60% to 80% of patients. In severe cases, the disturbance of sodium and potassium metabolism may be marked by depletion of sodium and water and severe, chronic dehydration.

With disease progression and acute hypotension, the patient develops addisonian crisis, which is characterized by cyanosis and the classic signs of circulatory shock: pallor, apprehension, rapid and weak pulse, rapid respirations, and low blood pressure. In addition, the patient may complain of headache, nausea, abdominal pain, and diarrhea and show signs of confusion and restlessness. Even slight overexertion, exposure to cold, acute infections, or a decrease in salt intake may lead to circulatory collapse, shock, and death if untreated. The stress of surgery or dehydration resulting from preparation for diagnostic tests or surgery may precipitate an addisonian or hypotensive crisis.

**Assessment and Diagnostic Findings**

Although the clinical manifestations presented appear specific, the onset of Addison’s disease usually occurs with nonspecific symptoms. The diagnosis is confirmed by laboratory test results. Laboratory findings include decreased blood glucose (hypoglycemia) and sodium (hypernatremia) levels, an increased serum potassium (hyperkalemia) level, and an increased white blood cell count (leukocytosis).
The diagnosis is confirmed by low levels of adrenocortical hormones in the blood or urine and decreased serum cortisol levels. If the adrenal cortex is destroyed, baseline values are low, and ACTH administration fails to cause the normal rise in plasma cortisol and urinary 17-hydroxycorticosteroids. If the adrenal gland is normal but not stimulated properly by the pituitary, a normal response to repeated doses of exogenous ACTH is seen, but no response follows the administration of metyrapone, which stimulates endogenous ACTH.

**Medical Management**

Immediate treatment is directed toward combating circulatory shock: restoring blood circulation, administering fluids and corticosteroids, monitoring vital signs, and placing the patient in a recumbent position with the legs elevated. Hydrocortisone (Solu-Cortef) is administered intravenously, followed with 5% dextrose in normal saline. Vasopressor amines may be required if hypotension persists.

Antibiotics may be administered if infection has precipitated adrenal crisis in a patient with chronic adrenal insufficiency. Additionally, the patient is assessed closely to identify other factors, stressors, or illnesses that led to the acute episode.

Oral intake may be initiated as soon as tolerated. Gradually, intravenous fluids are decreased when oral fluid intake is adequate to prevent hypovolemia. If the adrenal gland does not regain function, the patient needs lifelong replacement of corticosteroids and mineralocorticoids to prevent recurrence of adrenal insufficiency. The patient will require additional supplementary therapy with glucocorticoids during stressful procedures or significant illnesses to prevent addisonian crisis (Coursin & Wood, 2002). Additionally, the patient may need to supplement dietary intake with added salt during times of gastrointestinal losses of fluids through vomiting and diarrhea.

**Nursing Management**

**ASSESSING THE PATIENT**

The health history and examination focus on the presence of symptoms of fluid imbalance and on the patient’s level of stress. To detect inadequate fluid volume, the nurse monitors the blood pressure and pulse rate as the patient moves from a lying to a standing position. The nurse assesses the skin color and turgor for changes related to chronic adrenal insufficiency and hypovolemia. Other key assessments include checking for weight changes, muscle weakness, and fatigue and investigating any illness or stress that may have precipitated the acute crisis.

**MONITORING AND MANAGING ADDISONIAN CRISIS**

The patient at risk is monitored for signs and symptoms indicative of addisonian crisis. These symptoms are often the manifestations of shock: hypotension; rapid, weak pulse; rapid respiratory rate; pallor; and extreme weakness. The patient with addisonian crisis is at risk for circulatory collapse and shock (see Chap. 15 for management of the patient in shock); therefore, physical and psychological stressors must be avoided. These include exposure to cold, overexertion, infection, and emotional distress.

The patient with addisonian crisis requires immediate treatment with intravenous administration of fluid, glucose, and electrolytes, especially sodium; replacement of missing steroid hormones; and vasopressors. During acute addisonian crisis, the patient must avoid exertion; therefore, the nurse anticipates the patient’s needs and takes measures to meet them.

Careful monitoring of symptoms, vital signs, weight, and fluid and electrolyte status is essential to monitor the patient’s progress and return to a precrisis state. To reduce the risk of future episodes of addisonian crisis, efforts are made to identify and reduce the factors that may have led to the crisis.

**RESTORING FLUID BALANCE**

To provide information about fluid balance and the adequacy of hormone replacement, the nurse assesses the patient’s skin turgor, mucous membranes, and weight while instructing the patient to report increased thirst, which may indicate impending fluid imbalance. Lying, sitting, and standing blood pressures also provide information about fluid status. A decrease in systolic pressure (20 mm Hg or more) may indicate depletion of fluid volume, especially if accompanied by symptoms. The nurse encourages the patient to consume foods and fluids that will assist in restoring and maintaining fluid and electrolyte balance; along with the dietitian, the nurse assists the patient to select foods high in sodium during gastrointestinal disturbances and very hot weather.

The nurse instructs the patient and family to administer hormone replacement as prescribed and to modify the dosage during illness and other stressful occasions. Written and verbal instructions are provided about the administration of mineralocorticoid (Florinef) or corticosteroid (prednisone) as prescribed.

**IMPROVING ACTIVITY TOLERANCE**

Until the patient’s condition is stabilized, the nurse takes precautions to avoid unnecessary activity and stress that could precipitate another hypotensive episode. Efforts are made to detect signs of infection or the presence of other stressors. Even minor events or stressors may be excessive in patients with adrenal insufficiency. During the acute crisis, the nurse maintains a quiet, nonstressful environment and performs all activities (eg, bathing, turning) for the patient. Explaining all procedures to the patient and family will reduce their anxiety. Explaining the rationale for minimizing stress during the acute crisis assists the patient to increase activity gradually.

**PROMOTING HOME AND COMMUNITY-BASED CARE**

**Teaching Patients Self-Care.** Because of the need for lifelong replacement of adrenal cortex hormones to prevent addisonian crises, the patient and family members receive explicit verbal and written instructions about the rationale for replacement therapy and proper dosage. Additionally, they are instructed about how to modify the medication dosage and increase salt intake in times of illness, very hot weather, and other stressful situations. The patient also learns how to modify diet and fluid intake to help maintain fluid and electrolyte balance.

The patient and family are frequently prescribed preloaded, single-injection syringes of corticosteroid for use in emergencies. Careful instructions about how and when to use the injection are also provided. It is important to instruct the patient to inform other health care providers, such as dentists, about the use of corticosteroids, to wear a medical alert bracelet, and to carry information at all times about the need for corticosteroids. If the patient with Addison’s disease requires surgery, careful administration of fluids and corticosteroids is necessary before, during, and after surgery to prevent addisonian crisis.

The patient and family need to know the signs of excessive or insufficient hormone replacement. The development of edema or weight gain may signify too high a dose of hormone; postural hypotension (decrease in systolic blood pressure, lightheadedness,
Cushing’s syndrome is the ectopic production of ACTH by malignancies; bronchogenic carcinoma is the most common type of Cushing’s syndrome. If Cushing’s syndrome is a consequence of pituitary enlargement, the voice deepens. Libido is lost in men and women.

Pathophysiology

Cushing’s syndrome is commonly caused by use of corticosteroid medications and is infrequently due to excessive corticosteroid production by the adrenal cortex (Tierney et al., 2001). However, overproduction of endogenous corticosteroids may be caused by several mechanisms, including a tumor of the pituitary gland that produces ACTH and stimulates the adrenal cortex to increase its hormone secretion despite adequate amounts being produced. Primary hyperplasia of the adrenal glands in the absence of a pituitary tumor is less common. Another less common cause of Cushing’s syndrome is the ectopic production of ACTH by malignancies; bronchogenic carcinoma is the most common type of these malignancies. Regardless of the cause, the normal feedback mechanisms that control the function of the adrenal cortex become ineffective, and the usual diurnal pattern of cortisol is lost.

The signs and symptoms of Cushing’s syndrome are primarily a result of oversecretion of glucocorticoids and androgens (sex hormones), although mineralocorticoid secretion also may be affected.

Clinical Manifestations

When overproduction of the adrenal cortical hormone occurs, arrest of growth, obesity, and musculoskeletal changes occur along with glucose intolerance. The classic picture of Cushing’s syndrome in the adult is that of central-type obesity, with a fatty “buffalo hump” in the neck and supraclavicular areas, a heavy trunk, and relatively thin extremities. The skin is thin, fragile, and easily traumatized; ecchymoses (bruises) and striae develop. The patient complains of weakness and lassitude. Sleep is disturbed because of altered diurnal secretion of cortisol.

Excessive protein catabolism occurs, producing muscle wasting and osteoporosis. Kyphosis, backache, and compression fractures of the vertebrae may result. Retention of sodium and water occurs as a result of increased mineralocorticoid activity, producing hypertension and heart failure.

The patient develops a “moon-faced” appearance and may experience increased oiliness of the skin and acne. There is increased susceptibility to infection. Hyperglycemia or overt diabetes may develop. The patient may also report weight gain, slow healing of minor cuts, and bruises.

Women ages 20 to 40 years are five times more likely than men to develop Cushing’s syndrome. In females of all ages, virilization may occur as a result of excess androgens. Virilization is characterized by the appearance of masculine traits and the reversion of feminine traits. There is an excessive growth of hair on the face (hirsutism), the breasts atrophy, menses cease, the clitoris enlarges, and the voice deepens. Libido is lost in men and women.

Changes occur in mood and mental activity; psychosis may develop. Distress and depression are common and are increased by the severity of the physical changes that occur with this syndrome. If Cushing’s syndrome is a consequence of pituitary tumor, visual disturbances may occur because of pressure of the growing tumor on the optic chiasm. Chart 42-10 summarizes the changes associated with Cushing’s syndrome.

Assessment and Diagnostic Findings

Indicators of Cushing’s syndrome include an increase in serum sodium and blood glucose levels and a decreased serum concentration of potassium, a reduction in the number of blood eosinophils, and disappearance of lymphoid tissue. Measurements of plasma and urinary cortisol levels are obtained. Several blood samples may be collected to determine whether the normal diurnal variation in plasma levels is present; this variation is frequently absent in adrenal dysfunction. If several blood samples are required, they must be collected at the times specified and the time of collection must be noted on the requisition slip.

An overnight dexamethasone suppression test is the most widely used screening test for diagnosis of pituitary and adrenal causes of Cushing’s syndrome. It can be performed on an outpatient basis. Dexamethasone (1 mg) is administered orally at 11 pm, and a plasma cortisol level is obtained at 8 the next morning. Suppression of cortisol to less than 5 mg/dL indicates that the hypothalamic-pituitary-adrenal axis is functioning properly. Stress, obesity, depression, and medications such as antiseizure agents, estrogen, and rifampin can falsely elevate cortisol levels. Other diagnostic studies include a 24-hour urinary free cortisol level and a high-dose or low-dose dexamethasone suppression test. High-dose and low-dose suppression tests are similar to the overnight test but vary in dosage and timing.

Measurement of plasma ACTH by radioimmunoassay is used in conjunction with the high-dose suppression test to distinguish pituitary tumors from ectopic sites of ACTH production as the cause of Cushing’s syndrome. Elevation of both ACTH and cortisol level indicates pituitary or hypothalamic disease. Low ACTH with a high cortisol level indicates adrenal disease. A CT scan, ultrasound, or MRI may be performed to localize adrenal tissue and detect tumors of the adrenal gland.

Medical Management

If Cushing’s syndrome is caused by pituitary tumors rather than tumors of the adrenal cortex, treatment is directed at the pituitary gland. Surgical removal of the tumor by transphenoidal hypophysectomy (see Chap. 61) is the treatment of choice and has a 90% success rate (Rakel & Bope, 2001). Radiation of the pituitary gland also has been successful, although it may take several months for control of symptoms. Adrenalectomy is the treatment of choice in patients with primary adrenal hypertrophy.

Postoperatively, symptoms of adrenal insufficiency may begin to appear 12 to 48 hours after surgery because of reduction of the high levels of circulating adrenal hormones. Temporary replacement therapy with hydrocortisone may be necessary for several months until the adrenal glands begin to respond normally to the body’s needs. If both adrenal glands have been removed (bilateral adrenalectomy), lifetime replacement of adrenal cortex hormones is necessary.

Adrenal enzyme inhibitors (eg, metyrapone, aminoglutethimide, mitotane, ketoconazole) may be used to reduce hyperadrenalinism if the syndrome is caused by ectopic ACTH secretion by a tumor that cannot be eradicated. Close monitoring is necessary because symptoms of inadequate adrenal function may result and because of possible side effects of these medications.

If Cushing’s syndrome is a result of the administration of corticosteroids, an attempt is made to reduce or taper the medication to the minimum dosage needed to treat the underlying disease process (eg, autoimmune and allergic diseases and rejection of transplanted organs). Frequently, alternate-day therapy decreases the symptoms of Cushing’s syndrome and allows recovery of the adrenal glands’ responsiveness to ACTH.

Nursing Process: The Patient with Cushing’s Syndrome

Assessment

The health history and examination focus on the effects on the body of high concentrations of adrenal cortex hormones and on the inability of the adrenal cortex to respond to changes in

This woman with Cushing’s syndrome has several classic signs, including facial hair, buffalo hump, and moon face. From Rubin, E. & Farber, J. L. (1999). Pathology (3rd ed.). Philadelphia: Lippincott Williams & Wilkins.
cortisol and aldosterone levels. The history includes information about the patient’s level of activity and ability to carry out routine and self-care activities. The skin is observed and assessed for trauma, infection, breakdown, bruising, and edema. Changes in physical appearance are noted, and the patient’s responses to these changes are elicited. The nurse assesses the patient’s mental function, including mood, responses to questions, awareness of environment, and level of depression. The family is often a good source of information about gradual changes in the patient’s physical appearance as well as emotional status.

**Diagnosis**

**NURSING DIAGNOSES**

Based on all the assessment data, the major nursing diagnoses of the patient with Cushing’s syndrome include the following:

- Risk for injury related to weakness
- Risk for infection related to altered protein metabolism and inflammatory response
- Self-care deficit related to weakness, fatigue, muscle wasting, and altered sleep patterns
- Impaired skin integrity related to edema, impaired healing, and thin and fragile skin
- Disturbed body image related to altered physical appearance, impaired sexual functioning, and decreased activity level
- Disturbed thought processes related to mood swings, irritability, and depression

**COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS**

Based on assessment data, potential complications may include the following:

- Addisonian crisis
- Adverse effects of adrenocortical activity

**Planning and Goals**

The major goals for the patient include decreased risk for injury, decreased risk for infection, increased ability to carry out self-care activities, improved skin integrity, improved body image, improved mental function, and absence of complications.

**Nursing Interventions**

**DECREASING RISK FOR INJURY**

Establishing a protective environment will help to prevent falls, fractures, and other injuries to bones and soft tissues. The patient who is very weak may require assistance from the nurse in ambulating to prevent falls or bumping into sharp corners of furniture. Foods high in protein, calcium, and vitamin D are recommended to minimize muscle wasting and osteoporosis. Referral to a dietitian may assist the patient in selecting appropriate foods that are also low in sodium and calories.

**DECREASING RISK FOR INFECTION**

The patient should avoid unnecessary exposure to others with infections. The nurse frequently assesses the patient for subtle signs of infection because the anti-inflammatory effects of corticosteroids may mask the common signs of inflammation and infection.

**PREPARING THE PATIENT FOR SURGERY**

The patient is prepared for adrenalectomy, if indicated, and the postoperative course (see later discussion in this chapter). If Cushing’s syndrome is a result of a pituitary tumor, a transsphenoidal hypophysectomy may be performed (see Chap. 61). Diabetes mellitus and peptic ulcer are common in the patient with Cushing’s syndrome. Therefore, insulin therapy and medication to treat peptic ulcer may be initiated if needed. Before, during, and after surgery, blood glucose monitoring and assessment of stools for blood are carried out to monitor for appropriate intervention. If the patient has other symptoms of Cushing’s syndrome, these are considered in the preoperative preparation. For example, if the patient has experienced weight gain, special instruction is given about postoperative breathing exercises.

**ENCOURAGING REST AND ACTIVITY**

Weakness, fatigue, and muscle wasting make it difficult for the patient with Cushing’s syndrome to carry out normal activities. Yet the nurse should encourage moderate activity to prevent complications of immobility and promote increased self-esteem. Insomnia often contributes to the patient’s fatigue. It is important to help the patient plan and space rest periods throughout the day. Efforts are made to promote a relaxing, quiet environment for rest and sleep.

**PROMOTING SKIN INTEGRITY**

Meticulous skin care is necessary to avoid traumatizing the patient’s fragile skin. Use of adhesive tape is avoided because it can irritate the skin and tear the fragile tissue when the tape is removed. The nurse frequently assesses the skin and bony prominences and encourages and assists the patient to change positions frequently to prevent skin breakdown.

**IMPROVING BODY IMAGE**

If the cause of Cushing’s syndrome can be treated successfully, the major physical changes disappear in time. The patient may benefit from discussion of the effect the changes have had on his or her self-concept and relationships with others. Weight gain and edema may be modified by a low-carbohydrate, low-sodium diet, and a high-protein intake may reduce some of the other bothersome symptoms.

**IMPROVING THOUGHT PROCESSES**

Explanations to the patient and family members about the cause of emotional instability are important in helping them cope with the mood swings, irritability, and depression that may occur. Psychotic behavior may occur in a few patients and should be reported. The nurse encourages the patient and family members to verbalize their feelings and concerns.

**MONITORING AND MANAGING POTENTIAL COMPLICATIONS**

**Addisonian Crisis**

The patient with Cushing’s syndrome whose symptoms are treated by withdrawing corticosteroids, by adrenalectomy, or by removing a pituitary tumor is at risk for adrenal hypofunction and addisonian crisis. If high levels of circulating adrenal hormones have suppressed the function of the adrenal cortex, atrophy of the adrenal cortex is likely. If the circulating hormone level is decreased rapidly because of surgery or by abruptly stopping corticosteroid agents, manifestations of adrenal hypofunction and addisonian crisis may develop. Therefore, the patient
with Cushing’s syndrome is monitored closely for hypotension; rapid, weak pulse; rapid respiratory rate; pallor; and extreme weakness. Efforts are made to identify factors that may have led to the crisis.

The patient with Cushing’s syndrome who experiences highly stressful events, such as trauma or emergency surgery, is at increased risk for addisonian crisis because of long-term suppression of the adrenal cortex. The patient may require intravenous administration of fluid and electrolytes and corticosteroids before, during, and after treatment or surgery. If addisonian crisis occurs, the patient is treated for circulatory collapse and shock (see Chap. 15 for management of the patient in shock).

Adverse Effects of Adrenocortical Activity
The nurse assesses fluid and electrolyte status by monitoring laboratory values and daily weights. Because of the increased risk for glucose intolerance and hyperglycemia, blood glucose monitoring is initiated. The nurse reports elevated blood glucose levels to the physician so that treatment can be prescribed if indicated.

PROMOTING HOME AND COMMUNITY-BASED CARE
Teaching Patients Self-Care
The patient with Cushing’s syndrome and the patient’s family require teaching and support to enable them to prevent problems associated with the syndrome and to manage those that cannot be prevented. The nurse presents information verbally and in writing. If the disorder is a result of corticosteroid use for treatment of a chronic disease, the patient and family need to understand that stopping the corticosteroid use abruptly and without medical supervision is likely to result in acute adrenal insufficiency and reappearance of the underlying symptoms of the chronic disease. The nurse emphasizes the need to ensure an adequate supply of the corticosteroid, because running out of the medication and skipping doses can precipitate addisonian crisis. Refer to the later discussion, Therapeutic Uses of Corticosteroids, for more information.

The nurse stresses the need for dietary modifications to ensure adequate calcium intake without increasing the risk for hypertension, hyperglycemia, and weight gain. The patient and family may be taught to monitor blood pressure, blood glucose levels, and weight. Wearing a medical alert bracelet and notifying other health providers (eg, dentist) are important to alert others that the patient has Cushing’s syndrome (Chart 42-11).

Continuing Care
The need for follow-up depends on the origin and duration of the disease and its management. The patient who has been treated by adrenalectomy or removal of a pituitary tumor requires close monitoring to ensure that adrenal function has returned to normal and to ensure adequacy of circulating adrenal hormones. The patient who requires continued corticosteroid therapy is monitored to ensure understanding of the medications and the need for a dosage that treats the underlying disorder while minimizing the side effects. Home care referral may be indicated to ensure a safe environment that minimizes stress and risk for falls and other side effects. The home care nurse assesses the patient’s physical and psychological status and reports changes to the physician. The nurse also assesses the patient’s understanding of the medication regimen and the patient’s compliance with the regimen, and reinforces previous teaching about the medications and the importance of taking them as prescribed. The nurse emphasizes the importance of regular medical follow-up, the side effects and toxic effects of medications, and the need to wear medical identification with Addison’s and Cushing’s disease. Additionally, the nurse reminds the patient and family about the importance of health promotion activities and recommended health screening, including bone mineral density testing.

Evaluation
EXPECTED PATIENT OUTCOMES
Expected patient outcomes may include:

1. Decreases risk for injury
   a. Is free of fractures or soft tissue injuries
   b. Is free of ecchymotic areas
2. Decreases risk for infection
   a. Experiences no temperature elevation, redness, pain, or other signs of infection and inflammation
   b. Avoids contact with others who have infections

Chart 42-11
Home Care Checklist • The Patient With Cushing’s Syndrome

At the completion of the home care instruction, the patient or caregiver will be able to:

<table>
<thead>
<tr>
<th>Patient</th>
<th>Caregiver</th>

<td>✓✓</td>
</tr>
</tbody>
</table>

- State present and potential effects of Cushing’s syndrome on the body
- Identify signs and symptoms of excessive and insufficient adrenal hormone
- State the relationship between adrenal hormones, emotional state, and stress
- Identify methods for managing labile emotions
- Describe protective skin care measures and use of protective devices and practices
- State the importance of regular follow-up visits with primary health care provider
- State the purpose, dose, route, schedule, side effects, and precautions for prescribed medications (adrenocortical inhibitors)
- Identify need to wear medical alert identification and carry medical information card
- State importance of compliance with medical regimen
- State the need to contact health care provider before taking over-the-counter medications
- Identify foods high in potassium and low in sodium, calories, and carbohydrates
- Identify areas of activity limitations and impact on lifestyle
3. Increases participation in self-care activities
   a. Plans activities and exercises to allow alternating periods of rest and activity
   b. Reports improved well-being
   c. Is free of complications of immobility
4. Attains/maintains skin integrity
   a. Has intact skin, without evidence of breakdown or infection
   b. Exhibits decreased edema in extremities and trunk
   c. Changes position frequently and inspects bony prominences daily
5. Achieves improved body image
   a. Verbalizes feelings about changes in appearance, sexual function, and activity level
   b. States that physical changes are a result of excessive corticosteroids
6. Exhibits improved mental functioning
7. Absence of complications
   a. Exhibits normal vital signs and weight and is free of symptoms of addisonian crisis
   b. Identifies signs and symptoms of adrenocortical hypofunction that should be reported and measures to take in case of severe illness and stress
   c. Identifies strategies to minimize complications of Cushin’s syndrome
   d. Complies with recommendations for follow-up appointments and health screening.

PRIMARY ALDOSTERONISM

The principal action of aldosterone is to conserve body sodium. Under the influence of this hormone, the kidneys excrete less sodium and more potassium and hydrogen. Excessive production of aldosterone, which occurs in some patients with functioning tumors of the adrenal gland, causes a distinctive pattern of biochemical changes and a corresponding set of clinical manifestations that are diagnostic of this condition.

Clinical Manifestations

Patients with aldosteronism exhibit a profound decline in the serum levels of potassium (hypokalemia) and hydrogen ions (alkalosis), as demonstrated by an increase in pH and serum bicarbonate level. The serum sodium level is normal or elevated depending on the amount of water reabsorbed with the sodium. Hypertension is the most prominent and almost universal sign of aldosteronism, although it is the primary cause in less than 1% of cases of hypertension (Tierney et al., 2001).

Hypokalemia is responsible for the variable muscle weakness, cramping, and fatigue in patients with aldosteronism, as well as an inability on the part of the kidneys to acidify or concentrate the urine. Accordingly, the urine volume is excessive, leading to polyuria. Serum, by contrast, becomes abnormally concentrated, contributing to excessive thirst (polydipsia) and arterial hypertension. A secondary increase in blood volume and possible diuretics may be temporarily necessary because of suppression of the remaining adrenal gland by high levels of adrenal hormones. A normal serum glucose level is maintained with insulin, appropriate intravenous fluids, and dietary modifications.

Nursing management in the postoperative period includes frequent assessment of vital signs to detect early signs and symptoms of adrenal insufficiency and crisis or hemorrhage. Explaining all treatments and procedures, providing comfort measures, and providing rest periods can reduce the patient’s stress and anxiety level.

Corticosteroid Therapy

Corticosteroids are used extensively for adrenal insufficiency and are also widely used in suppressing inflammation and autoimmune reactions, controlling allergic reactions, and reducing the rejection process in transplantation. Commonly used corticosteroid preparations are listed in Table 42-4. Their anti-inflammatory and antiallergy actions make corticosteroids effective in treating rheumatic or connective tissue diseases, such as rheumatoid arthritis and systemic lupus erythematosus. They are also frequently used in the treatment of asthma, multiple sclerosis, and other autoimmune disorders.

High doses appear to allow patients to tolerate high degrees of stress. Such antistress action may be caused by the ability of corticosteroids to aid circulating vasopressor substances in keeping

Assessment and Diagnostic Findings

In addition to a high or normal serum sodium level and low serum potassium level, diagnostic studies indicate high serum aldosterone levels and low serum renin levels. The measurement of the aldosterone excretion rate after salt loading is a useful diagnostic test for primary aldosteronism. The renin–aldosterone stimulation test and bilateral adrenal venous sampling are useful in differentiating the cause of primary aldosteronism. Antihypertensive medication may be discontinued up to 2 weeks prior to testing.

Medical Management

Treatment of primary aldosteronism usually involves surgical removal of the adrenal tumor through adrenalectomy. Hypokalemia resolves for all patients after surgery, but hypertension may persist. Spironolactone may be prescribed to control hypertension.

SURGICAL MANAGEMENT: ADRENALECTOMY

Adrenalectomy may be used in treating adrenal tumors, primary Cushin’s syndrome, and aldosteronism. For adrenal tumors, all of the endocrine disturbances associated with a hypersecreting tumor of the adrenal cortex or medulla can be relieved completely by surgical removal of the involved gland. Adrenalectomy is performed through an incision in the flank or the abdomen. In general, the postoperative care resembles that for other abdominal surgery. However, the patient is susceptible to fluctuations in adrenocortical hormones and requires administration of corticosteroids, fluids, and other agents to maintain blood pressure and prevent acute complications. If the adrenalectomy is bilateral, replacement of corticosteroids will be lifelong; if one adrenal gland is removed, replacement therapy may be temporarily necessary because of suppression of the remaining adrenal gland by high levels of adrenal hormones. A normal serum glucose level is maintained with insulin, appropriate intravenous fluids, and dietary modifications.

Assessment and Diagnostic Findings
The dosage of corticosteroids is determined by the nature and chronicity of the illness as well as the patient’s other medical problems. Rheumatoid arthritis, bronchial asthma, and multiple sclerosis are chronic disorders that corticosteroids do not cure; however, these medications may be useful when other measures do not provide adequate control of symptoms. In addition, corticosteroids may be used to treat acute exacerbations of these disorders.

In such situations, the adverse effects of corticosteroids are weighed against the patient’s current problems. These medications may be used for a period but then are gradually reduced or tapered as the symptoms subside. The nurse plays an important role in providing encouragement and understanding during the times the patient may experience (or is apprehensive about experiencing) recurrence of symptoms while taking smaller doses.

**Treatment of Acute Conditions**

Acute flare-ups and crises are treated with large doses of corticosteroids. Examples include emergency treatment for bronchial obstruction in status asthmaticus and septic shock from septicemia caused by gram-negative bacteria. Other measures, such as anti-infective agents or medications, are also used with corticosteroids to treat shock and other major symptoms. At times, corticosteroids are continued past the acute flare-up stage to prevent serious complications.

**Eye Treatment**

A different problem exists when corticosteroids are used in treating eye infections. Outer eye infection can be treated by topical application of eye drops because these do not cause systemic toxicity. However, long-term application may cause an increase in intraocular pressure, which leads to glaucoma in some patients. In some patients, prolonged use of corticosteroids leads to cataract formation.

**Dermatologic Disorders**

Topical administration of corticosteroids in the form of creams, ointments, lotions, and aerosols is especially effective in many dermatologic disorders. It may be more effective in some conditions to use occlusive dressings around the affected part to achieve maximum absorption of the medication. Penetration and absorption are also increased if the medication is applied when the skin is hydrated or moist (eg, immediately after bathing).

Absorption of topical agents varies with body location. For example, absorption is greater through the layers of skin on the scalp, face, and genital area than on the forearm; as a result, use of topical agents on these sites increases the risk for side effects of the medication. The availability of over-the-counter topical corticosteroids increases the risk for side effects in patients who are unaware of their potential risks. Excessive use of these agents, especially on large surface areas of inflamed skin, can lead to decreased therapeutic effects and increased side effects.

**Dosage**

Attempts have been made to determine the best time to administer pharmacologic doses of steroids. When symptoms have been controlled on a 6-hour or 8-hour program, a once-daily or every-other-day schedule may be implemented. In keeping with the natural secretion of cortisol, the best time of the day for the total corticosteroid dose is in the early morning from 7 to 8 AM. Large-dose therapy at 8 AM, when the gland is most active, produces maximal suppression of the gland. A large 8 AM dose is more physiologic because it allows the body to escape effects of the steroids from 4 PM to 6 AM, when serum levels are normally low, hence minimizing cushingoid effects. If symptoms of the disorder being treated are suppressed, alternate-day therapy is helpful in reducing pituitary-adrenal suppression in patients requiring prolonged therapy. Some patients report discomfort associated with symptoms of their primary illness on the second
TAPERING

Corticosteroid dosages are reduced gradually (tapered) to allow normal adrenal function to return and to prevent steroid-induced adrenal insufficiency. Up to 1 year or more after use of corticosteroids, the patient is still at risk for adrenal insufficiency in times of stress. For example, if surgery for any reason is necessary, the patient is likely to require intravenous corticosteroids during and after surgery to reduce the risk for acute adrenal crisis. Patients receiving corticosteroids must have an adequate supply of medication on hand, so that they do not miss a scheduled dose and increase their risk for adrenal insufficiency. Table 42-5 provides an overview of the effects of corticosteroid therapy and their nursing implications.

Table 42-5 • Side Effects of Corticosteroid Therapy and Implications for Practice

Critical Thinking Exercises

1. Your patient has just been diagnosed with hyperthyroidism. Because she is wary of radioactive substances and unwilling to take radioactive iodine, she has been scheduled for a thyroidectomy in 6 weeks. Prior to surgery, she will receive antithyroid medication to control her symptoms. What preoperative teaching is needed for the patient and her family? What nursing interventions are warranted preoperatively and during the postoperative period?

2. Your 70-year-old patient has a diagnosis of bronchogenic carcinoma. He reports that his voiding has decreased in frequency and volume recently and he is being evaluated for possible syndrome of inappropriate antidiuretic hormone secretion (SIADH). The patient and his family are asking for explanations about the syndrome and about methods of managing it. What nursing interventions and patient and family teaching are warranted when caring for this patient?

3. Your 24-year-old patient has been receiving corticosteroids for treatment of ulcerative colitis. She is distraught about the changes in her appearance related to corticosteroids and is talking about stopping the corticosteroids because of the weight gain and other symptoms she has experienced. What interventions are appropriate at this time? What teaching should be provided to the patient and her family about the use of corticosteroids?

4. A 46-year-old patient received radiation therapy 5 years ago for treatment of thyroid cancer. She is being seen for her annual gynecologic examination. What questions are important in assessing her to evaluate her thyroid status? Identify the rationale for each area of assessment and how it relates to thyroid function.

5. Your patient, a 30-year-old woman with two small children, lives within 2 miles of a nuclear power plant. She expresses anxiety and concern about the risks to herself and her children if there is a terrorist attack on the plant. What intervention is warranted? Provide your rationale and describe the explanation you would give to the woman.

6. Your patient has pheochromocytoma and is scheduled to undergo adrenalectomy. What preoperative and postoperative nursing priorities are important in his care? What assessment parameters are important during the prep- and postoperative periods?

Assessment of Renal and Urinary Tract Function

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Describe the anatomy and physiology of the upper and lower urinary tracts.
2. Identify the assessment parameters used for determining the status of upper and lower urinary tract function.
3. Describe the diagnostic studies used to determine upper and lower urinary tract function.
4. Initiate education and preparation for patients undergoing assessment of the urinary system.
5. Discuss the role of the kidney in regulating fluid and electrolyte balance, acid–base balance, and blood pressure.
Proper function of the urinary system is essential to life. Dysfunction of the kidneys and lower urinary tract is common and may occur at any age and with varying levels of severity. Assessment of upper and lower urinary tract function is part of every health examination and necessitates an understanding of the anatomy and physiology of the urinary system as well as of the effect of changes in the system on other physiologic functions.

Anatomic and Physiologic Overview

The urinary system comprises the kidneys, ureters, bladder, and urethra. A thorough understanding of the urinary system is necessary for assessing individuals with acute or chronic urinary dysfunction and implementing appropriate nursing care.

ANATOMY OF THE UPPER AND LOWER URINARY TRACTS

The urinary system—the structures of which precisely maintain the internal chemical environment of the body—perform various excretory, regulatory, and secretory functions.

Kidneys

The kidneys are a pair of brownish-red structures located retroperitoneally (behind and outside the peritoneal cavity) on the posterior wall of the abdomen from the 12th thoracic vertebra to the 3rd lumbar vertebra in the adult (Fig. 43-1). An adult kidney weighs 120 to 170 g (about 4.5 oz) and is 12 cm (about 4.5 inches) long, 6 cm wide, and 2.5 cm thick. The kidneys are well protected by the ribs, muscles, Gerota’s fascia, perirenal fat, and the renal capsule, which surround each kidney.

The kidney consists of two distinct regions, the renal parenchyma and the renal pelvis. The renal parenchyma is divided into the cortex and the medulla. The cortex contains the glomeruli, proximal and distal tubules, and cortical collecting ducts and their adjacent peritubular capillaries. The medulla resembles conical pyramids. The pyramids are situated with the base facing the concave surface of the kidney and the apex facing the hilum, or pelvis. Each kidney contains approximately 8 to 18 pyramids. The pyramids drain into 4 to 13 minor calices that, in turn, drain into 2 to 3 major calices that open directly into the renal pelvis.

The hilum, or pelvis, is the concave portion of the kidney through which the renal artery enters and the renal vein exits. The renal artery (arising from the abdominal aorta) divides into smaller and smaller vessels, eventually forming the afferent arteriole. The afferent arteriole branches to form the glomerulus, which is the capillary bed responsible for glomerular filtration. Blood leaves the glomerulus through the efferent arteriole and flows back to the inferior vena cava through a network of capillaries and veins.

Each kidney contains about 1 million nephrons, the functional units of the kidney. Each kidney is capable of providing adequate renal function if the opposite kidney is damaged or becomes nonfunctional. The nephron consists of a glomerulus containing afferent and efferent arterioles, Bowman’s capsule, proximal tubule, loop of Henle, distal tubule, and collecting ducts (Fig. 43-2). Collecting ducts converge into papillae, which empty into the minor calices, which drain into three major calices that open directly into the renal pelvis.

Nephrons are structurally divided into two types: cortical and juxtamedullary. Cortical nephrons are found in the cortex of the kidney, and juxtamedullary nephrons sit adjacent to the medulla. The juxtamedullary nephrons are distinguished by their long loops of Henle and the vasa recta, long capillary loops that dip into the medulla of the kidney.

The glomerulus is composed of three filtering layers: the capillary endothelium, the basement membrane, and the epithelium. The glomerular membrane normally allows filtration of fluid and small molecules yet limits passage of larger molecules, such as blood cells and albumin. Kidney function begins to decrease at a rate of approximately 1% each year beginning at approximately age 30.

Ureters, Bladder, and Urethra

Urine, which is formed within the nephrons, flows into the ureter, a long fibromuscular tube that connects each kidney to the bladder. The ureters are narrow, muscular tubules, each 24 to 30 cm long, that originate at the lower portion of the renal pelvis and terminate in the bladder.

Glossary

- **aldoendo**: hormone synthesized and released by the adrenal cortex; causes the kidneys to reabsorb sodium
- **antidiuretic hormone (ADH)**: hormone secreted by the posterior pituitary gland; causes the kidneys to reabsorb more water
- **anuria**: total urine output less than 50 mL in 24 hours
- **bacteriuria**: bacteria in the urine; bacterial count higher than 100,000 colonies/mL
- **clearance**: volume of plasma that the kidneys can clear of a specific solute (e.g., creatinine); expressed in milliliters per minute
- **creatinine**: endogenous waste product of muscle energy metabolism
- **dysuria**: painful or difficult urination
- **frequency**: voiding more frequently than every 3 hours
- **glomerulus**: tuft of capillaries forming part of the nephron through which filtration occurs
- **glomerular filtration rate (GFR)**: volume of plasma filtered at the glomerulus into the kidney tubules each minute; normal rate is approximately 120 mL/min
- **hematuria**: red blood cells in the urine
- **micturition**: urination or voiding
- **nephron**: structural and functional unit of the kidney responsible for urine formation
- **nocturia**: awakening at night to urinate
- **oliguria**: total urine output less than 400 mL in 24 hours
- **osmolality**: number of particles dissolved per kilogram of urine; expression of the degree of concentration of the urine
- **proteinuria**: protein in the urine
- **pyuria**: pus in the urine
- **specific gravity**: reflects the weight of particles dissolved in the urine; expression of the degree of concentration of the urine
- **tubular reabsorption**: movement of a substance from the kidney tubule into the blood in the peritubular capillaries or vasa recta
- **tubular secretion**: movement of a substance from the blood in the peritubular capillaries or vasa recta into the kidney tubule
- **urea nitrogen**: nitrogenous end product of protein metabolism
- **urinary incontinence**: involuntary loss of urine
- **Valsalva leak-point pressure (VLPP)**: amount of abdominal pressure against the bladder that causes the urethra to open and leak urine
- **vesicoureteral reflux**: backflow of urine from the bladder into the ureters
reflux, which is the retrograde, or backward, movement of urine from the bladder, up the ureter, toward the kidney. During voiding (micturition), increased intravesical pressure keeps the ureterovesical junction closed and keeps urine within the ureters. As soon as micturition is completed, intravesical pressure returns to its normal low baseline value, allowing efflux of urine to resume. Therefore, the only time that the bladder is completely empty is in the last seconds of micturition before efflux of urine resumes.

The three areas of narrowing within the ureters have a propensity toward obstruction because of renal calculi (kidney stones) or stricture. Obstruction of the ureteropelvic junction is the most serious because of its close proximity to the kidney and the risk of associated kidney dysfunction. The left ureter is slightly shorter than the right. The lining of the ureters is made up of transitional cell epithelium called urothelium. As in the bladder, the urothelium prevents reabsorption of urine. The movement of urine from the renal pelves through the ureters into the bladder is facilitated by peristaltic waves (occurring about one to five times per minute) from contraction of the smooth muscle in the ureter wall (Walsh, Retik, Vaughan & Wein, 1998).

The urinary bladder is a muscular, hollow sac located just behind the pubic bone. Adult bladder capacity is about 300 to 600 mL of urine. In infancy, the bladder is found within the abdomen. In adolescence and through adulthood, the bladder assumes its position in the true pelvis. The bladder is characterized by its central, hollow area called the vesicle, which has two inlets (the ureters) and one outlet (the urethrovesical junction), which is surrounded by the bladder neck. The wall of the bladder comprises four layers. The outermost layer is the adventitia, which is made up of connective tissue. Immediately beneath the adventitia is a smooth muscle layer known as the detrusor. Beneath the detrusor is a smooth muscle tunic known as the lamina propria, which serves as an interface between the detrusor and the innermost layer, the urothelium. The urothelium layer is specialized, transitional cell epithelium, containing a membrane that is impermeable to water. The urothelium prevents the reabsorption of urine stored in the bladder. The bladder neck contains bundles of involuntary smooth muscle that form a portion of the urethral sphincter known as the internal sphincter. The portion of the sphincteric mechanism that is under voluntary control is the external urinary sphincter at the anterior urethra, the segment most distal from the bladder (Walsh et al., 1998).
The urethra arises from the base of the bladder: In the male, it passes through the penis; in the female, it opens just anterior to the vagina. In the male, the prostate gland, which lies just below the bladder neck, surrounds the urethra posteriorly and laterally.

PHYSIOLOGY OF THE UPPER AND LOWER URINARY TRACTS

The urinary system performs various roles that are essential for normal bodily homeostasis (Chart 43-1). These functions include urine formation; excretion of waste products; regulation of electrolyte, acid, and water excretion; and autoregulation of blood pressure.

Urine Formation

Urine is formed in the nephrons through a complex three-step process: glomerular filtration, tubular reabsorption, and tubular secretion. Figure 43-3 illustrates the three processes of urine formation and typical values of water and electrolytes associated with each process. The various substances normally filtered by the glomerulus, reabsorbed by the tubules, and excreted in the urine include sodium, chloride, bicarbonate, potassium, glucose, urea, creatinine, and uric acid. Within the tubule, some of these substances are selectively reabsorbed into the blood. Others are secreted from the blood into the filtrate as it travels down the tubule. Some substances, such as glucose, are completely reabsorbed in the tubule and normally do not appear in the urine. Amino acids and glucose are usually filtered at the level of the glomerulus and reabsorbed so that neither is excreted in the urine. Glucose, however, appears in the urine (glycosuria) if the amount of glucose in the blood and glomerular filtrate exceeds the amount that the tubules are able to reabsorb. Normally, glucose is completely reabsorbed when the blood glucose level is less than 200 mg/dL (11 mmol/L). In diabetes, when the blood glucose level exceeds the kidneys’ reabsorption capacity, glucose appears in the urine. Glososuria is also common in pregnancy.

Protein molecules are also generally not found in the urine; however, low-molecular-weight proteins (globulins and albumin) may periodically be excreted in small amounts. Transient proteinuria in amounts less than 150 mg/dL is considered normal and does not require further evaluation. Persistent proteinuria usually signifies damage to the glomeruli.

Physiology/Pathophysiology

![Diagram of Urine Formation](Image)

**Figure 43-3** Urine is formed in the nephrons in a three-step process: filtration, reabsorption, and excretion. Water, electrolytes, and other substances, such as glucose and creatinine, are filtered by the glomerulus; varying amounts of these are reabsorbed in the renal tubule, or excreted in the urine. Typical normal volumes of these substances during the steps of urine formation appear above. Wide variations may occur in the values depending on diet.
The steps of urine formation are:

- Glomerular filtration: The normal blood flow through the kidneys is about 1,200 mL/min. As blood flows into the glomerulus from an afferent arteriole, filtration occurs. The filtered fluid, also known as filtrate or ultrafiltrate, then enters the renal tubules. Under normal conditions, about 20% of the blood passing through the glomeruli is filtered into the nephron, amounting to about 180 L/day of filtrate. The filtrate normally consists of water, electrolytes, and other small molecules, because water and small molecules are allowed to pass, whereas larger molecules stay in the bloodstream. Efficient filtration depends on adequate blood flow maintaining a consistent pressure through the glomerulus. Many factors can alter this blood flow and pressure, including hypotension, decreased oncotic pressure in the blood, and increased pressure in the renal tubules from an obstruction.
- Tubular reabsorption and tubular secretion: The second and third steps of urine formation occur in the renal tubules and are called tubular reabsorption and tubular secretion. In tubular reabsorption, a substance moves from the filtrate back into the peritubular capillaries or vasa recta. In tubular secretion, a substance moves from the peritubular capillaries or vasa recta into tubular filtrate. Of the 180 L (45 gallons) of filtrate that the kidneys produce each day, 99% is reabsorbed into the bloodstream, resulting in 1,000 to 1,500 mL of urine each day. Although most reabsorption occurs in the proximal tubule, reabsorption occurs along the entire tubule. Reabsoption and secretion in the tubule frequently involve passive and active transport and may require the use of energy. Filtrate becomes concentrated in the distal tubule and collecting ducts under the influence of antidiuretic hormone (ADH) and becomes urine, which then enters the renal pelvis.

**Excretion of Waste Products**

The kidney functions as the body’s main excretory organ, eliminating the body’s metabolic waste products. The major waste product of protein metabolism is urea, of which about 25 to 30 g is produced and excreted daily. All of this urea must be excreted in the urine; otherwise it will accumulate in body tissues. Other waste products of metabolism that must be excreted are creatinine, phosphates, and sulfates. Uric acid, formed as a waste product of purine metabolism, is also eliminated in the urine. The kidneys serve as the primary mechanism for excreting drug metabolites.

**Regulation of Electrolyte Excretion**

When the kidneys are functioning normally, the volume of electrolytes excreted per day is exactly equal to the amount ingested. For example, the average American daily diet contains 6 to 8 g each of sodium chloride (salt) and potassium chloride. Nearly all of this is excreted in the urine. Electrolyte excretion includes sodium and potassium.

**SODIUM**

More than 99% of the water and sodium filtered at the glomeruli is reabsorbed into the blood by the time the urine leaves the body. Water from the filtrate follows the reabsorbed sodium to maintain osmotic balance. By regulating the amount of sodium (and therefore water) reabsorbed, the kidney can regulate the volume of body fluids. If more sodium is excreted than ingested, dehydration results; if less sodium is excreted than ingested, fluid retention results.

The regulation of sodium volume excreted depends on aldosterone, a hormone synthesized and released from the adrenal cortex. With increased aldosterone in the blood, less sodium is excreted in the urine because aldosterone fosters renal reabsorption of sodium. Release of aldosterone from the adrenal cortex is largely under the control of angiotensin II. Angiotensin II levels are in turn controlled by renin, an enzyme that is released from specialized cells in the kidneys (Fig. 43-4). This complex system is activated when pressure in the renal arterioles falls below normal levels, as occurs with shock, dehydration, or decreased sodium chloride delivery to the tubules. Activation of this system increases the retention of water and expansion of intravascular fluid volume.

**Regulation of Acid Excretion**

The catabolism, or breakdown, of proteins results in the production of acid compounds, in particular phosphoric and sulfuric acids. The normal diet also includes a certain amount of acid materials. Unlike carbon dioxide (CO₂), phosphoric and sulfuric acids are nonvolatile and cannot be eliminated by the lungs. Because accumulation of these acids in the blood would lower its pH (making the blood more acidic) and inhibit cell function, they must be excreted in the urine. A person with normal kidney function excretes about 70 mEq of acid each day. The kidney is able to excrete some of this acid directly into the urine until the urine pH reaches 4.5, which is 1,000 times more acidic than blood.

More acid, however, usually needs to be eliminated from the body than can be excreted directly as free acid in the urine. These excess acids are bound to chemical buffers so they can be excreted in the urine. Two important chemical buffers are phosphate ions and ammonia (NH₃). When buffered with acid, ammonia becomes ammonium (NH₄). Phosphate is present in the glomerular filtrate, and ammonia is produced by the cells of the renal tubules and secreted into the tubular fluid. Through the buffering process, the kidney is able to excrete large quantities of acid in a bound form, without further lowering the pH of the urine.

**Regulation of Water Excretion**

Regulation of the amount of water excreted is also an important function of the kidney. With high fluid intake, a large volume of dilute urine is excreted. Conversely, with a low fluid intake, a small volume of concentrated urine is excreted. A person normally ingests about 1 to 2 L of water per day, and normally all but 400 to 500 mL of this fluid is excreted in the urine. The remainder is lost from the skin, from the lungs during breathing, and in the feces.

**Osmolality**

The degree of dilution or concentration of the urine can be measured in terms of osmolality, the number of particles (electrolytes
and other molecules) dissolved per kilogram of urine. The filtrate in the glomerular capillary normally has the same osmolality as the blood, with a value of about 300 mOsm/L (300 mmol/L). As the filtrate passes through the tubules and collecting ducts, the osmolality may vary from 50 to 1,200 mOsm/L, reflecting the maximal diluting and concentrating abilities of the kidney. When a person is dehydrated or retaining fluid, less water is excreted, and proportionately more particles are present in the urine, giving the urine a concentrated appearance and a high osmolality. When a person excretes a large volume of water, the particles are diluted. The urine appears dilute and the osmolality is low. Certain substances can alter the volume of water excreted and are described as osmotically active. When these substances are filtered, they pull water across the glomeruli and tubules and increase the volume of urine. Glucose and proteins are two examples of osmotically active molecules. Urine osmolality normally ranges from 300 to 1,100 mOsm/kg; however, after a 12-hour fluid restriction, that range narrows to 500 to 850 mOsm/kg. This wide range of normal makes the test valuable only when the kidneys’ concentrating and diluting abilities are questioned.

**SPECIFIC GRAVITY**

**Specific gravity** is a measurement of the kidney’s ability to concentrate urine. It compares the weight of urine (weight of particles) to the weight of distilled water, which has a specific gravity of 1.000. Normal urine specific gravity is 1.010 to 1.025 when fluid intake is normal. Factors that may interfere with an accurate urine specific gravity reading include radiopaque contrast agents, glucose, and proteins. Cold urine specimens may also produce a falsely high reading. Several methods can be used to measure specific gravity:

- Multiple-test dipstick (most common method), with a specific reagent area for specific gravity
- Urinometer (least accurate method), in which urine is placed in a small cylinder, and the urinometer is floated in the urine; a specific gravity reading is obtained at the meniscus level of the urine
- Refractometer, an instrument used in a laboratory setting, which measures differences in the speed of light passing through air and the urine sample

Urine specific gravity depends largely on hydration status. When fluid intake decreases, specific gravity normally increases. With high fluid intake, specific gravity decreases. In patients with kidney disease, urine specific gravity does not vary with fluid intake, and the patient’s urine is said to have a fixed specific gravity. Disorders or conditions that cause a low urine specific gravity include diabetes insipidus, glomerulonephritis, and severe renal damage. Those that can cause an increased specific gravity include diabetes mellitus, nephrosis, and excessive fluid loss.

**ANTIDIURETIC HORMONE**

ADH (also known as vasopressin) regulates water excretion and urine concentration in the tubule by varying the amount of water that is reabsorbed. ADH is a hormone that is secreted by the pos-
terior part of the pituitary gland in response to changes in osmolality of the blood. With decreased water intake, blood osmolality tends to rise and stimulate ADH release. ADH then acts on the kidney, increasing reabsorption of water and thereby returning the osmolality of the blood to normal. With excess water intake, the secretion of ADH by the pituitary is suppressed; therefore, less water is reabsorbed by the kidney tubule. This latter situation leads to increased urine volume (diuresis).

A dilute urine with a fixed specific gravity (about 1.010) or fixed osmolality (about 300 mOsm/L) indicates an inability to concentrate and dilute the urine, a common early sign of kidney disease.

**Autoregulation of Blood Pressure**

Regulation of blood pressure is also a function of the kidney. Specialized vessels of the kidney called the vasa recta constantly monitor blood pressure as blood begins its passage into the kidney. When the vasa recta detect a decrease in blood pressure, specialized juxtагlomerular cells near the afferent arteriole, distal tubule, and efferent arteriole secrete the hormone renin. Renin converts angiotensinogen to angiotensin I, which is then converted to angiotensin II, the most powerful vasoconstrictor known. The vasocostriction causes the blood pressure to increase. The adrenal cortex secretes aldosterone in response to stimulation by the pituitary gland, which, in turn, is in response to poor perfusion or increasing serum osmolality. The result is an increase in blood pressure. When the vasa recta recognize the increase in blood pressure, renin secretion stops. Failure of this feedback mechanism is one of the primary causes of hypertension.

**Renal Clearance**

Renal clearance refers to the ability of the kidneys to clear solutes from the plasma. A 24-hour collection of urine is the primary test of renal clearance used to evaluate how well the kidney performs this important excretory function. Clearance depends on several factors: how quickly the substance is filtered across the glomerulus, how much of the substance is reabsorbed along the tubules, and how much of the substance is secreted into the tubules. It is possible to measure the renal clearance of any substance, but the one measure that is particularly useful is the creatinine clearance.

Creatinine is an endogenous waste product of skeletal muscle that is filtered at the glomerulus, passed through the tubules with minimal change, and excreted in the urine. Hence, creatinine clearance is a good measure of the glomerular filtration rate (GFR). To calculate creatinine clearance, a 24-hour urine specimen is collected. Midway through the collection, the serum creatinine level is measured. The following formula is then used to calculate the creatinine clearance:

\[
\frac{(Volume\ of\ urine\ [mL/min] \times \ urine\ creatinine\ [mg/dL])}{serum\ creatinine\ (mg/dL)}
\]

The normal adult GFR is about 100 to 120 mL/min (1.67 to 2.0 mL/sec). Creatinine clearance is an excellent measure of renal function; as renal function declines, creatinine clearance decreases.

**Regulation of Red Blood Cell Production**

When the kidneys sense a decrease in the oxygen tension in renal blood flow, they release erythropoietin. Erythropoietin stimulates the bone marrow to produce red blood cells (RBCs), thereby increasing the amount of hemoglobin available to carry oxygen.

**Vitamin D Synthesis**

The kidneys are also responsible for the final conversion of inactive vitamin D to its active form, 1,25-dihydroxycholecalciferol. Vitamin D is necessary for maintaining normal calcium balance in the body.

**Secretion of Prostaglandins**

The kidneys also produce prostaglandin E (PGE) and prostacyclin (PGI), which have a vasodilatory effect and are important in maintaining renal blood flow.

**Urine Storage**

The bladder is the reservoir for urine. Both bladder filling and emptying are mediated by coordinated sympathetic and parasympathetic nervous system control mechanisms involving the detrusor muscle and the bladder outlet. In an infant, bladder filling and emptying are mediated within the micturition center in the pons area of the brain stem. By the time a child is 3 to 4 years old, the cerebral cortex is mature enough to cause a conscious awareness of bladder filling. This conscious awareness of bladder filling occurs as a result of sympathetic neuronal pathways that travel via the spinal cord to the level of T10-12, where peripheral, hypogastric nerve innervation allows for continued bladder filling. As bladder filling continues, stretch receptors in the bladder wall are activated, coupled with the desire to void. This information from the detrusor muscle is relayed back to the cerebral cortex via the parasympathetic pelvic nerves at the level of S2 through S4. Normally, the pressure in the bladder remains low even as the urine accumulates, due to the bladder’s compliance, or ability to expand with increasing urine volumes (Appell, 1999).

Bladder compliance is due in part to the smooth muscle lining of the bladder and collagen deposits within the wall of the bladder, as well as to neuronal mechanisms that inhibit the detrusor muscle from contracting (specifically, adrenergic receptors that mediate relaxation). To maintain adequate kidney filtration rates, bladder pressure during filling must remain lower than 40 cm H2O. Ordinarily, the first sensation of bladder filling occurs when there is approximately 100 to 150 mL of urine in the bladder. The first sensation of bladder fullness is transmitted to the central nervous system when the bladder has reached approximately half of its capacity, about 200 to 300 mL in adults, and an initial desire to void occurs. A marked sense of fullness with a strong desire to void usually occurs when the bladder contains 350 mL or more of urine (“functional capacity”). During anesthesia, the average adult bladder under pressure of 60 cm H2O can hold 1,500 to 2,000 mL (“anatomic capacity”). During normal circumstances, with appropriate bladder wall innervation, capacity would never reach this level because of the tremendous pain and pressure that such fullness would cause. Neurologic changes to the bladder at the level of the supraspinal, spinal, or bladder wall itself can cause abnormally high volumes of urine to be stored due to a decreased or absent urge to void. Under normal circumstances with average fluid intake of approximately 1,500 to 2,000 mL per day, the bladder should be able to store urine for periods of 2 to 4 hours at a time during the day. At night, the release of vasopressin in response to decreased fluid intake causes less production of urine that is more concentrated. This phenomenon usually allows the bladder to continue filling for periods of 6 to 8 hours in adolescents and adults. In older individuals, decreasing bladder compliance and vasopressin levels cause nighttime bladder filling to decrease to periods ranging from 3 to 6 hours (Appell, 1999).
Bladder Emptying

Micturition (voiding) normally occurs approximately eight times in a 24-hour period. It is activated via the micturition reflex arc within the sympathetic and parasympathetic nervous system, which causes a coordinated sequence of events. Initiation of voiding occurs when the efferent pelvic nerve, which originates in S2 to S4, stimulates the bladder to contract, resulting in complete relaxation of the striated urethral sphincter and followed by a fall in urethral pressure, contraction of the detrusor muscle, opening of the vesicle neck and proximal urethra, and flow of urine. This coordinated effort by the parasympathetic system is mediated by muscarinic and, to a lesser extent, cholinergic receptors within the detrusor muscle. The pressure generated in the bladder during micturition is about 20 to 40 cm H₂O in females. It is somewhat higher and more variable in males ages 45 and older due to the normal hyperplasia of the cells of the middle lobes of the prostate gland that surround the proximal urethra. An obstruction of the bladder outlet, such as in advanced benign prostatic hyperplasia (BPH), results in abnormally high voiding pressure with a slow, prolonged flow of urine. In females, gravity drains any urine remaining in the urethra; in males, voluntary muscle contractions expel the urine (Wein, 2001).

If the spinal pathways from the brain to the urinary system are destroyed (eg, after a spinal cord injury), reflex contraction of the bladder is maintained, but voluntary control over the process is lost. In both situations, the detrusor muscle can contract and expel urine, but the contractions are generally insufficient to empty the bladder completely, so residual urine (urine left in the bladder after voiding) remains. Normally, residual urine amounts to no more than 50 mL in the middle-aged adult and less than 50 to 100 mL in the older adult. Chronic urine retention is more prevalent in older men and women (Gray, 2000b).

Assessment

Obtaining a comprehensive health history, which includes an assessment of risk factors, is the first step in assessing a patient with upper or lower urinary tract dysfunction. Various diseases or clinical situations can place a patient at increased risk for urinary tract dysfunction. Data collection about previous health problems or diseases provides the health care team with useful information for evaluating the patient’s current urinary status. Risk factors for specific disorders and kidney and lower urinary tract dysfunction are discussed in Chart 43-2 and in Chapters 44 and 45.

HEALTH HISTORY

Obtaining a urologic health history requires excellent communication skills because many patients are embarrassed or uncomfortable discussing genitourinary function or symptoms. It is important to use language the patient can understand and to avoid medical jargon. It is also important to review risk factors, particularly with those at risk. For example, the nurse needs to be aware that multiparous women delivering their children vaginally are at high risk for stress urinary incontinence, which if severe enough can also lead to urge incontinence. Elderly women and persons with neurologic disorders such as diabetic neuropathy, multiple sclerosis, or Parkinson’s disease often have incomplete emptying of the bladder with urinary stasis, which may result in urinary tract infection or increasing bladder pressure leading to overflow incontinence, hydronephrosis, pyelonephritis, or renal insufficiency.

Persons with a family history of urinary tract problems are at increased risk for renal disorders. Persons with diabetes who have consistent hypertension are at risk for renal dysfunction (Bakris, Williams, Dworkin et al., 2000). Older men are at risk for prostatic enlargement, which causes urethral obstruction and which can result in urinary tract infections and renal failure (Degler, 2000). Moreover, many persons with a history of systemic lupus erythematosus (SLE) develop lupus nephritis (Smith, Fortune-Faulkner & Spurbeck, 2000). When obtaining the health history, the nurse should inquire about the following:

- The patient’s chief concern or reason for seeking health care, the onset of the problem, and its effect on the patient’s quality of life
- The location, character, and duration of pain, if present, and its relationship to voiding; factors that precipitate pain, and those that relieve it
- History of urinary tract infections, including past treatment or hospitalization for urinary tract infection
- Fever or chills
- Previous renal or urinary diagnostic tests or use of indwelling urinary catheters

- Dysuria and when it occurs during voiding (at initiation or termination of voiding)
- Hesitancy, straining, or pain during or after urination
- Urinary incontinence (stress incontinence, urge incontinence, overflow incontinence, or functional incontinence)
- Hematuria or change in color or volume of urine
- Nocturia and its date of onset
- Renal calculi (kidney stones), passage of stones or gravel in urine
- Female patients: number and type (vaginal or cesarean) of deliveries; use of forceps; vaginal infection, discharge, or irritation; contraceptive practices
- Presence or history of genital lesions or sexually transmitted diseases
- Habits: use of tobacco, alcohol, or recreational drugs
- Any prescription and over-the-counter medications (including those prescribed for renal or urinary problems)

Gerontologic Considerations

A thorough medication history is especially important for elderly patients, for whom the increased occurrence of chronic illness often necessitates polypharmacy (concurrent use of multiple medications). Aging affects the way the body absorbs, metabolizes, and excretes drugs, thus placing the elderly patient at risk for adverse reactions, including compromised renal function.

Other key information to obtain while gathering the health history includes an assessment of the patient’s psychosocial status, level of anxiety, perceived threats to body image, available support systems, and sociocultural patterns. Obtaining this information during the initial and subsequent nursing assessments enables the nurse to uncover special needs, misunderstandings, lack of knowledge, and need for patient teaching. Pain, changes in voiding, and gastrointestinal symptoms are particularly suggestive of urinary tract disease. Dysfunction of the kidney can produce a complex array of symptoms throughout the body.

Unexplained Anemia

Gradual kidney dysfunction can be insidious in its presentation, although fatigue is a common symptom. Fatigue, shortness of breath, and exercise intolerance all result from the condition known as “anemia of chronic disease.” Although hematocrit has been the blood test of choice when assessing a patient for anemia, the 2001 Kidney Disease Outcomes Quality Initiative: Management of Anemia Guidelines recommend that anemia be quantified using hemoglobin level rather than hematocrit, because that measurement is a better assessment of circulating oxygen (Eschbach, 2001).

Genetics in Nursing Practice—Urinary Tract Disorders

Various conditions that affect the renal system and urinary tract function are influenced by genetic factors. Some examples of these genetic disorders are:
- Congenital absence of the vas deferens (caused by CFTR gene mutation for cystic fibrosis)
- Cystic, dysplastic kidneys
- Familial Wilms’ tumor
- Horseshoe kidney
- Polycystic kidney (autosomal dominant gene)
- Nephrosis of later onset
- Renal cystic disease in tuberous sclerosis complex

Nursing Assessments

Family History
- Inquire about other family members with renal and/or urinary tract malformations.
- Ask about family history of kidney disease with onset in third to fifth decade (polycystic kidney, autosomal dominant gene).
- Identify family history of male infertility and cystic fibrosis (congenital absence of vas deferens).
- Be alert for family members with history of early-onset renal (Wilms’ tumor) or other cancers.

Physical Assessment
- Be alert for signs and symptoms of renal disease at an early age (hematuria, hypertension, abdominal mass).
- Assess for clinical findings suggesting that renal disease is a component of a genetic syndrome (eg, seizures, mental retardation, skin involvement).

Management Issues Specific to Genetics
- Inquire whether DNA mutation or other genetic testing has been performed on an affected family member.
- If indicated, refer for genetic counseling and evaluation so that the family can discuss concerns regarding inheritance, risks to other family members, availability of genetic testing, and gene-based interventions.
- Offer appropriate genetic information and resources (eg, Genetic Alliance web site).
- Provide support to families newly diagnosed with genetic-related renal and/or kidney disease.

National Organization of Rare Disorders http://www.rarediseases.org—a directory of support groups and information for patients and families with rare genetic disorders
Pain

Genitourinary pain is usually caused by distention of some portion of the urinary tract because of obstructed urine flow or inflammation and swelling of tissues. Severity of pain is related to the sudden onset rather than the extent of distention. Table 43-1 lists the various types of genitourinary pain, characteristics of the pain, associated signs and symptoms, and possible causes. However, kidney disease does not always involve pain. It tends to be diagnosed because of other symptoms that cause a patient to seek health care, such as pedal edema, shortness of breath, and changes in urine elimination (Gray, 2001).

Changes in Voiding

Voiding (micturition) is normally a painless function occurring approximately eight times in a 24-hour period. The average person voids 1,200 to 1,500 mL of urine in 24 hours, although this amount varies depending on fluid intake, sweating, environmental temperature, vomiting, or diarrhea. Common problems associated with voiding include frequency, urgency, dysuria, hesitancy, incontinence, enuresis, polyuria, oliguria, and hematuria. These problems and others described in Table 43-2. Increased urinary urgency and frequency coupled with decreasing urine volumes strongly suggest urine retention. Depending on the acuity of the onset of these symptoms, immediate bladder emptying via catheterization and evaluation are necessary to prevent kidney dysfunction (Gray, 2000a).

Gastrointestinal Symptoms

Gastrointestinal symptoms may occur with urologic conditions because of shared autonomic and sensory innervation and reflexes. The anatomic relation of the right kidney to the colon, duodenum, head of the pancreas, common bile duct, liver, and gallbladder may cause gastrointestinal disturbances. The proximity of the left kidney to the colon (splenic flexure), stomach, pancreas, and spleen may also result in intestinal symptoms. The most common signs and symptoms include nausea, vomiting, diarrhea, abdominal discomfort, and abdominal distention. Urologic symptoms can mimic such disorders as appendicitis, peptic ulcer disease, or cholecystitis, thus making diagnosis difficult, especially in the elderly, because of decreased neurologic innervation to this area (Kuebler, 2001; Wade-Elliot, 1999).

PHYSICAL EXAMINATION

Several body systems can affect upper and lower urinary tract dysfunction, and that dysfunction can affect several end organs; therefore, a head-to-toe assessment is indicated. Areas of emphasis include the abdomen, suprapubic region, genitalia and lower back, and lower extremities.

Direct palpation of the kidneys may help determine their size and mobility. The correct position for palpation is presented in Figure 43-5. It may be possible to feel the smooth, rounded lower pole of the kidney between the hands, although the right kidney is easier to feel because it is somewhat lower than the left one. In obese patients, palpation of the kidneys is generally more difficult.

Renal dysfunction may produce tenderness over the costovertebral angle, which is the angle formed by the lower border of the 12th, or bottom, rib and the spine. The abdomen (just slightly to the right and left of midline in both upper quadrants) is auscultated to assess for bruits (low-pitched murmurs that indicate renal arteriopathy or an aortic aneurysm). The abdomen is also assessed for the presence of peritoneal fluid, which may occur with kidney dysfunction.

The bladder should be percussed after the patient voids to check for residual urine. Percussion of the bladder begins at the midline just above the umbilicus and proceeds downward. The sound changes from tympanic to dull when percussing over the bladder. The bladder, which can be palpated only if it is moderately distended, feels like a smooth, firm, round mass rising out of the abdomen, usually at midline (Fig. 43-6). Dullness to percussion of the bladder following voiding indicates incomplete bladder emptying.

</table>
In older men, benign prostatic hyperplasia (BPH) is a common cause of urinary dysfunction. Because the signs and symptoms of prostate cancer can mimic those of BPH, the prostate gland is palpated by digital rectal examination (DRE) as part of the yearly physical examination in men ages 50 and older (45 if there is a family history of prostate cancer). In addition, a blood specimen is obtained to test the prostate specific antigen (PSA) level annually; the results of the DRE and PSA are then correlated. Blood is drawn for PSA before the DRE because manipulation of the prostate can cause the PSA level to rise temporarily. The inguinal area is examined for enlarged nodes, an inguinal or femoral hernia, or varicocele (varicose veins of the spermatic cord) (American Foundation for Urological Disease, 2000; Degler, 2001).

In women, the vulva, urethral meatus, and vagina are examined. The urethra is palpated for diverticula and the vagina is assessed for adequate estrogen effect and any of five types of herniation (Goolsby, 2001). Urethrocystectomy is the bulging of the anterior vaginal wall into the urethra. Cystocele is the herniation of the bladder wall into the vaginal vault. The cervix bulging into the vaginal vault is referred to as pelvic prolapse. Enterocoele is herniation of the bowel into the posterior vaginal wall, and rectocele is the herniation of the rectum into the vaginal wall. These prolapses are graded depending on the degree of herniation (see Chap. 47 for more information).

The woman is asked to cough and perform a Valsalva maneuver to assess the urethra’s system of muscular and ligament support. If urine leakage occurs, the index and middle fingers of the examiner’s gloved hand are used to support either side of the urethra as the woman is asked to repeat these maneuvers. This is called the Marshall-Boney maneuver.

If no urine leakage is detected when external support is provided to the urethra, poor pelvic floor support—referred to as urethral hypermobility—is identified as the suspected cause of the urinary incontinence. Stress urinary incontinence (SUI) is graded based on its severity. Grade 1 and Grade 2 SUI relate to the degree of urethral hypermobility. Grade 3, the most severe form of SUI, refers to the inability of the urethral walls to remain compressed with abdominal pressure such as a cough or Valsalva maneuver. Grade 3 is referred to as intrinsic sphincter deficiency (ISD) (Albaugh, 1999).

If some residual leakage of urine is noted despite support, ISD is suspected. Urethral hypermobility may be suspected when Q-tip test results are positive. The Q-tip test involves gently placing a well-lubricated Q-tip into the urethra until resistance is noted, then gently pulling back on the Q-tip until resistance is felt. The female patient is asked to cough and perform the Valsalva maneuver. If there is an upward (positive deflection) of the test results are positive. The Q-tip test involves gently placing a well-lubricated Q-tip into the urethra until resistance is no longer noted, then gently pulling back on the Q-tip until resistance is felt. The female patient is asked to cough and perform the Valsalva maneuver. If there is an upward (positive deflection) of the Q-tip, urethral hypermobility is at least one of the causes for the type of incontinence referred to as stress incontinence (see Chap. 44) (Albaugh, 1999).

The patient is assessed for edema and changes in body weight. Edema may be observed, particularly in the face and dependent parts of the body, such as the ankles and sacral areas, and suggests fluid retention. An increase in body weight commonly accompanies edema. A 1-kg weight gain equals approximately 1,000 mL of fluid.
to decreased bladder wall contractility, due to myogenic or neurogenic causes, or structurally, related to bladder outlet obstruction, as in BPH. Vaginal and urethral tissues atrophy (become thinner) in aging women due to decreased estrogen levels. This causes decreased blood supply to the urogenital tissues, causing urethral and vaginal irritation and urinary incontinence.

Urinary incontinence is the most common reason for admission to skilled nursing facilities. Many older individuals and their families are unaware that urinary incontinence stems from many causes. The nurse needs to inform the patient and family that with appropriate evaluation, urinary incontinence can often be managed at home and in many cases can be eliminated (Degler, 2000). Many treatments are available for urinary incontinence in the elderly, including noninvasive, behavioral interventions that the individual or the caregiver can carry out (Kincade, Peckous & Busby-Whitehead, 2001). Treatment modalities for urinary incontinence are described in further detail in Chapter 44.

Preparation of the elderly patient for diagnostic tests must be managed carefully to prevent dehydration, which might precipitate renal failure in a patient with marginal renal reserve. Limitations in mobility may affect an elderly patient’s ability to void adequately or to consume an adequate volume of fluids. The patient may limit fluid intake to minimize the frequency of voiding or the risk of incontinence. Teaching the patient and family about the dangers of an inadequate fluid intake is an important role of the nurse caring for the elderly patient.

Diagnostic Evaluation

URINALYSIS AND URINE CULTURE

The urinalysis provides important clinical information on kidney function and helps diagnose other diseases, such as diabetes. The urine culture determines if bacteria are present in the urine, as well as their strains and concentration. Urine culture and sensitivity also identify the antimicrobial therapy that is best suited for the particular strains identified, taking into consideration the antibiotics that have the best rate of resolution in that particular geographic region. Appropriate evaluation of any abnormality can assist in detecting serious underlying diseases.

Urine examination includes the following:

- Urine color (Table 43-3)
- Urine clarity and odor
- Urine pH and specific gravity
- Tests to detect protein, glucose, and ketone bodies in the urine (proteinuria, glycosuria, and ketonuria, respectively)
- Microscopic examination of the urine sediment after centrifuging to detect RBCs (hematuria), white blood cells, casts (cylindruria), crystals (crystalluria), pus (pyuria), and bacteria (bacteriuria)

Significance of Findings

Several abnormalities, such as hematuria and proteinuria, produce no symptoms but may be detected during a routine urinalysis using a dipstick. Normally, about 1 million RBCs pass into the urine daily, which is equivalent to one to three RBCs per high-power field. Hematuria (more than three RBCs per high-power field) can develop from an abnormality anywhere along the genitourinary tract. Common causes include acute infection (cystitis, urethritis, or prostatitis), renal calculi, and neoplasm. Other causes include systemic disorders, such as bleeding disorders; malignant lesions; and medications, such as warfarin (Coumadin).
and heparin. Although hematuria may initially be detected using a dipstick test, further microscopic evaluation is necessary (National Institute of Diabetes & Digestive & Kidney Diseases [NIDDK], 1999).

Protein in the urine (proteinuria) may be a benign finding, or it may signify serious disease. Occasional loss of up to 150 mg/day of protein in the urine, primarily albumin and Tamm-Horsfall protein, is considered normal and usually does not require further evaluation. A dipstick examination, which can detect from 30 to 1,000 mg/dL of protein, should be used as a screening test only, because urine concentration, pH, hematuria, and radiocontrast materials all affect the results. Because dipstick analysis does not detect protein concentrations of less than 30 mg/dL, the test cannot be used for early detection of diabetic nephropathy. Microalbuminuria (excretion of 20 to 200 mg/dL of protein in the urine) is an early sign of diabetic nephropathy. Common benign causes of transient proteinuria are fever, strenuous exercise, and prolonged standing.

Causes of persistent proteinuria include glomerular diseases, malignancies, collagen diseases, diabetes mellitus, preeclampsia, hypothyroidism, heart failure, exposure to heavy metals, and use of medications, such as nonsteroidal anti-inflammatory drugs (NSAIDs) and angiotensin-converting enzyme inhibitors (NIDDK, 2000).

**RENAL FUNCTION TESTS**

Renal function tests are used to evaluate the severity of kidney disease and to assess the patient’s clinical progress. These tests also provide information on the effectiveness of the kidney in carrying out its excretory function. Renal function test results may be within normal limits until the GFR is reduced to less than 50% of normal. Renal function can be assessed most accurately if several tests are performed and their results analyzed together. Common tests of renal function include renal concentration tests, creatinine clearance, and serum creatinine and blood urea nitrogen levels. Table 43-4 describes the purpose and normal ranges for each. Other helpful tests for evaluating renal function are serum electrolyte levels.

**X-RAY FILMS AND OTHER IMAGING MODALITIES**

**Kidney, Ureter, and Bladder Studies**

An x-ray study of the abdomen or kidney, ureters, and bladder (KUB) may be performed to delineate the size, shape, and position of the kidneys and to reveal any abnormalities, such as calculi (stones) in the kidneys or urinary tract, hydronephrosis (distention of the pelvis of the kidney), cysts, tumors, or kidney displacement by abnormalities in surrounding tissues.

**General Ultrasonography**

Ultrasonography is a noninvasive procedure that uses sound waves passed into the body through a transducer to detect abnormalities of internal tissues and organs. Structures of the urinary system create characteristic ultrasonographic images. Abnormalities such as fluid accumulation, masses, congenital malformations, changes in organ size, or obstructions can be identified. During the test, the lower abdomen and genitalia may need to be exposed. Ultrasonography requires a full bladder; therefore, fluid intake should be encouraged before the procedure. Because of its sensitivity, ultra-

**Nursing Research Profile 43-1**

Diary-Keeping as a Predictor of Urinary Incontinence Treatment Success

**Purpose**

Urinary incontinence (UI) affects approximately 13 million Americans. The usual behavioral interventions include a program of pelvic muscle strengthening. Despite the well-documented safety and efficacy of this intervention, high rates of patient withdrawal have been reported. The purpose of this study was to determine the characteristics that best predict completion of behavioral treatment for UI in an outpatient setting.

**Study Sample and Design**

The sample for this descriptive study was obtained from a university-affiliated clinic that provided community-based care for adults with UI. To be eligible for inclusion in the study, subjects had to be 50 years old or older. They also had to complete an initial clinic visit and perform pelvic floor exercises augmented with biofeedback prescribed by the clinician. Data collected by review of clinic records for the study included demographic data (age, gender, race, and education level), incontinence-related variables (initial treatment goal; frequency, amount, and duration of urine loss; type of incontinence and presence of nocturia), service-related variables (distance to clinic, source of referral to the UI clinic, previous efforts to get provider help for UI, and completion of a 7-day bladder diary), and health-related variables (number of comorbidities and of prescription medications). Program completion was the study’s dependent variable.

**Findings**

Of the 156 patients in the UI clinic, 98 met the study criteria. The majority of participants were older, Caucasian, well-educated women with mainly urge and mixed urinary incontinence of many years’ duration. Over half (55.1%) of the patients completed the treatment program. The only characteristic that differed significantly (p ≤ 0.0001) in those who completed the program and those who did not was completion of a 7-day bladder diary. Those who completed the 7-day bladder diary before the program study was initiated were much more likely to complete the program than those who did not complete the diary.

**Nursing Implications**

Completion of a 7-day voiding diary before beginning a behavioral continence program is usually considered pivotal for an accurate record of day-to-day bladder status, and the data obtained from the review are important in assessing the effectiveness of the treatment. Clinicians need to assess the patient’s reasons for unwillingness or inability to complete the diary. Protocols or treatment strategies should be developed for this subset of patients so that they can benefit from this noninvasive, effective treatment modality for UI.

---

Computed tomography (CT) and magnetic resonance imaging (MRI) are noninvasive techniques that provide excellent cross-sectional views of the kidney and urinary tract. They are used in evaluating genitourinary masses, nephrolithiasis, chronic renal infections, renal or urinary tract trauma, metastatic disease, and soft tissue abnormalities. The nurse should explain to the patient that a sedative may be prescribed. Claustrophobia is often a problem, especially with MRI. Patient preparation for the MRI includes removal of any metallic objects, such as jewelry or clothing with metallic clasps. Credit cards should be kept away from the MRI area because of their magnetic strips. MRI is contraindicated in patients with pacemakers, surgical clips, or any metallic objects anywhere in the body. Occasionally, an oral or intravenous radiopaque contrast material is used in CT scanning to enhance visualization. Nursing care guidelines for patient preparation and test precautions for any imaging procedure requiring a contrast agent (also called contrast medium) are explained in Chart 43-3.

---

Bladder Ultrasonography

Bladder ultrasonography is a noninvasive method of measuring urine volume in the bladder. It may be indicated for urinary frequency, inability to void after removal of an indwelling urinary catheter, measurement of postvoiding residual urine volume, inability to void postoperatively, or assessment of the need for catheterization during the initial stages of an intermittent catheterization training program. Portable, battery-operated devices are available for bedside use. The scan head is placed on the patient’s abdomen and directed toward the bladder. The device automatically calculates and displays urine volume.
Nuclear Scans

Nuclear scans require injection of a radioisotope (technetium-99m-labeled compound or iodine-131 hippurate) into the circulatory system; the isotope is then monitored as it moves through the blood vessels of the kidneys. A scintillation camera is placed behind the kidney with the patient in a supine, prone, or seated position. Hypersensitivity to the radioisotope is rare. The technetium scan provides information about kidney perfusion; the hippurate scan provides information about kidney function.

Nuclear scans are used to evaluate acute and chronic renal failure, renal masses, and blood flow before and after kidney transplantation. The radioisotope is injected at a specified time before the study to achieve the proper concentration in the kidneys. After the procedure is completed, the patient is encouraged to drink fluids to promote excretion of the radioisotope by the kidneys.

Intravenous Urography

Intravenous urography includes various tests such as excretory urography, intravenous pyelography (IVP), and infusion drip pyelography. A radiopaque contrast agent is administered intravenously. An IVP, or intravenous urogram, shows the kidneys, ureter, and bladder via x-ray imaging as dye moves through the upper and then lower urinary system. A nephrotomogram may be carried out as part of the study to visualize different layers of the kidney and the

Patient Care During Urologic Testing With Contrast Agents

For some patients, contrast agents are nephrotoxic and allergenic. The following guidelines can help the nurse and other caregivers respond quickly in the event of a problem.

**Nursing Actions for Room Preparation**
- Have emergency equipment and medications available in case the patient has an anaphylactic reaction to the contrast agent. Emergency supplies include epinephrine, corticosteroids, and vasopressors; oxygen; and airway and suction equipment.

**Nursing Actions for Patient Preparation**
- Obtain the patient’s allergy history with emphasis on allergy to iodine, shellfish, and other seafood, because many contrast agents contain iodine.
- Notify physician and radiologist if the patient is allergic or suspected to be allergic to iodine.
- Obtain health history. Contrast agents should be used with caution in older patients and patients who have diabetes mellitus, multiple myeloma, renal insufficiency, or volume depletion.
- Inform the patient that he or she may experience a temporary feeling of warmth, flushing of the face, and an unusual flavor (seafood) in the mouth when the contrast agent is infused.
- Monitor patient closely for allergic reaction and monitor urine output.

Nuclear Scans

Nuclear scans require injection of a radioisotope (technetium-99m–labeled compound or iodine-131 hippurate) into the circulatory system; the isotope is then monitored as it moves through the blood vessels of the kidneys. A scintillation camera is placed behind the kidney with the patient in a supine, prone, or seated position. Hypersensitivity to the radioisotope is rare. The technetium scan provides information about kidney perfusion; the hippurate scan provides information about kidney function.

Nuclear scans are used to evaluate acute and chronic renal failure, renal masses, and blood flow before and after kidney transplantation. The radioisotope is injected at a specified time before the study to achieve the proper concentration in the kidneys. After the procedure is completed, the patient is encouraged to drink fluids to promote excretion of the radioisotope by the kidneys.

Intravenous Urography

Intravenous urography includes various tests such as excretory urography, intravenous pyelography (IVP), and infusion drip pyelography. A radiopaque contrast agent is administered intravenously. An IVP, or intravenous urogram, shows the kidneys, ureter, and bladder via x-ray imaging as dye moves through the upper and then lower urinary system. A nephrotomogram may be carried out as part of the study to visualize different layers of the kidney and the
diffuse structures within each layer and to differentiate solid masses or lesions from cysts in the kidneys or urinary tract.

Intravenous urography may be used as the initial assessment of any suspected urologic problem, especially lesions in the kidneys and ureters. It also provides a rough estimate of renal function. After the contrast agent (sodium diatrizoate or meglumine diatrizoate) is administered intravenously, multiple x-rays are obtained to visualize drainage structures.

Infusion drip pyelography requires an intravenous infusion of a large volume of a dilute contrast agent to opacify the renal parenchyma and fill the urinary tract. This examination method is useful when prolonged opacification of the drainage structures is desired so that tomograms (body-section radiography) can be made. Images are obtained at specified intervals after the start of the infusion. These images show the filled and distended collecting system. The patient preparation is the same as for excretory urography, except that fluids are not restricted.

**Retrograde Pyelography**

In retrograde pyelography, catheters are advanced through the ureters into the renal pelvis by means of cystoscopy. A contrast agent is then injected. Retrograde pyelography is usually performed if intravenous urography provides inadequate visualization of the collecting systems. It may also be used before extracorporeal shock-wave lithotripsy or in patients with urologic cancer who need follow-up and are allergic to intravenous contrast agents. Possible complications include infection, hematuria, and perforation of the ureter. Retrograde pyelography is used infrequently because of improved techniques in excretory urography.

**Cystography**

Cystography aids in evaluating vesicoureteral reflux (backflow of urine from the bladder into one or both ureters) and assessing the patient for bladder injury. A catheter is inserted into the bladder, and a contrast agent is instilled to outline the bladder wall. The contrast agent may leak through a small bladder perforation stemming from bladder injury, but such leakage is usually harmless. Cystography can also be performed with simultaneous pressure recordings inside the bladder.

**Voiding Cystourethrogram**

Voiding cystourethrogram uses fluoroscopy to visualize the lower urinary tract and assess urine storage in the bladder. It is commonly used as a diagnostic tool to identify vesicoureteral reflux (between bladder and ureter). A urethral catheter is inserted, and a contrast agent is instilled into the bladder. When the bladder is full and the patient feels the urge to void, the catheter is removed, and the patient voids. Retrograde urethrography, in which a contrast agent is injected retrograde into the urethra, is always performed before urethral catheterization if urethral trauma is suspected.

**Renal Angiography**

A renal angiogram, or renal arteriogram, provides an image of the renal arteries. The femoral (or axillary) artery is pierced with a needle, and a catheter is threaded up through the femoral and iliac arteries into the aorta or renal artery. A contrast agent is injected to opacify the renal arterial supply. Angiography is used to evaluate renal blood flow in suspected renal trauma, to differentiate renal cysts from tumors, and to evaluate hypertension. It is used preoperatively for renal transplantation. Before the procedure, a laxative may be prescribed to evacuate the colon so that unobstructed x-rays can be obtained. Injection sites (groin for femoral approach or axilla for axillary approach) may be shaved. The peripheral pulse sites (radial, femoral, and dorsalis pedis) are marked for easy access during postprocedural assessment. The patient is informed that there may be a brief sensation of heat along the course of the vessel when the contrast agent is injected.

After the procedure, vital signs are monitored until stable. If the axillary artery was the injection site, blood pressure measurements are taken on the opposite arm. The injection site is examined for swelling and hematoma. Peripheral pulses are palpated, and the color and temperature of the involved extremity are noted and compared with those of the uninvolved extremity. Cold compresses may be applied to the injection site to decrease edema and pain. Possible complications include hematoma formation, arterial thrombosis or dissection, false aneurysm formation, and altered renal function.

**UROLOGIC ENDOSCOPIC PROCEDURES**

Endourology, or urologic endoscopic procedures, can be performed in one of two ways: using a cystoscope inserted into the urethra, or percutaneously, through a small incision.

The cystoscopic examination is used to directly visualize the urethra and bladder. The cystoscope, which is inserted through the urethra into the bladder, has a self-contained optical lens system that provides a magnified, illuminated view of the bladder (Fig. 43-7). The use of a high-intensity light and interchangeable lenses allows excellent visualization and permits still and motion pictures to be taken. The cystoscope is manipulated to allow complete visualization of the urethra and bladder as well as the ureteral orifices and prostatic urethra. Small ureteral catheters can be passed through the cystoscope, allowing assessment of the ureters and the pelvis of each kidney.
The cystoscope also permits the urologist to obtain a urine specimen from each kidney to evaluate its function. Cup forceps can be inserted through the cystoscope for biopsy. Calculi may be removed from the urethra, bladder, and ureter using cystoscopy. If a lower tract cystoscopy is performed, the patient is usually awake and the procedure is usually no more uncomfortable than a catheterization. To minimize post-test urethral discomfort, viscous lidocaine is usually injected several minutes prior to the study. If the cystoscopy includes examination of the upper tracts, a sedative may be administered before the procedure. General anesthesia is usually administered to ensure that there are no involuntary muscle spasms when the scope is being passed through the ureters or kidney.

The nurse describes the examination to the patient and family to prepare them and to allay their fears. If an upper cystoscopy is to be performed, the patient is usually kept NPO (nothing by mouth) for several hours beforehand, unless the examination is being done to assess structural integrity following trauma.

Postprocedural management is directed at relieving any discomfort resulting from the examination. Some burning on voiding, blood-tinged urine, and urinary frequency from trauma to the mucous membrane can be expected. Moist heat to the lower abdomen and warm sitz baths are helpful in relieving pain and relaxing the muscles.

After a cystoscopic examination, the patient with obstructive pathology may experience urine retention if the instruments used during the examination caused edema. The nurse carefully monitors the patient with prostatic hyperplasia for urine retention. Warm sitz baths and antispasmodic medication, such as flavoxate (Urispas), may be prescribed to relieve temporary urine retention due to poor relaxation of the urinary sphincter; however, intermittent catheterization may be necessary for a few hours after the examination. The nurse monitors the patient for signs and symptoms of urinary tract infection. Because edema of the urethra secondary to local trauma may obstruct urine flow, the patient is also monitored for signs and symptoms of obstruction (NIDDK, 2001a).

BIOPSY

Renal and Ureteral Brush Biopsy

Brush biopsy techniques provide specific information when abnormal x-ray findings of the ureter or renal pelvis raise questions about whether the defect is a tumor, a stone, a blood clot, or an artifact. First, a cystoscopic examination is conducted. Then, a ureteral catheter is introduced, followed by a biopsy brush that is passed through the catheter. The suspected lesion is brushed back and forth to obtain cells and surface tissue fragments for histologic analysis.

After the procedure, intravenous fluids may be administered to help clear the kidneys and prevent clot formation. Urine may contain blood (usually clearing in 24 to 48 hours) from oozing at the brushing site. Postoperative renal colic occasionally occurs and responds to analgesics.

Kidney Biopsy

Biopsy of the kidney is used in diagnosing and evaluating the extent of kidney disease. Indications for biopsy include unexplained acute renal failure, persistent proteinuria or hematuria, transplant rejection, and glomerulopathies. A small section of renal cortex is obtained either percutaneously (needle biopsy) or by open biopsy through a small flank incision. Before the biopsy is carried out, coagulation studies are conducted to identify any risk for postbiopsy bleeding. Contraindications to a kidney biopsy include bleeding tendencies, uncontrolled hypertension, and a solitary kidney.

PROCEDURE

The patient may be placed on a fasting regimen 6 to 8 hours before the test. An intravenous line is established. A urine specimen is obtained and saved for comparison with the postbiopsy specimen.

If a needle biopsy is to be performed, the patient is instructed to breathe in and hold that breath (to prevent the kidney from moving) while the needle is being inserted. The sedated patient is placed in a prone position with a sandbag under the abdomen. The skin at the biopsy site is infiltrated with a local anesthetic. The biopsy needle is introduced just inside the renal capsule of the outer quadrant of the kidney. The location of the needle may be confirmed by fluoroscopy or by ultrasound, in which case a special probe is used.

With open biopsy, a small incision is made over the kidney, allowing direct visualization. Preparation for an open biopsy is similar to that for any major abdominal surgery (NIDDK, 2001b).

NURSING INTERVENTIONS

After the tissue specimen is obtained, pressure is applied to the biopsy site. The patient may be kept in a prone position immediately after biopsy and on bed rest for 6 to 8 hours to minimize the risk of bleeding.

Monitoring and Managing Potential Complications. Potential postbiopsy complications include persistent hematuria, fistula or aneurysm formation, or laceration of organs or blood vessels adjacent to the kidney. The nurse monitors the patient closely for hematuria, which may appear soon after biopsy. The kidney is a highly vascular organ, and about one fourth of the entire cardiac output circulates through it in about 1 minute. The passage of the biopsy needle punctures the kidney capsule, and bleeding can occur in the perirenal space. Usually the bleeding subsides on its own, but a large amount of blood can accumulate in this space in a short time without noticeable signs until cardiovascular collapse is evident.

Nursing interventions after a kidney biopsy include:

- Monitor vital signs every 5 to 15 minutes for the first hour to detect early signs of bleeding, and then with decreasing frequency as indicated.
- Be alert for signs and symptoms that suggest bleeding, including a rise or fall in blood pressure, tachycardia, anorexia, vomiting, and the development of a dull, aching discomfort in the abdomen.
- Immediately report any symptoms of backache, shoulder pain, or dysuria.

Flank pain may occur but usually represents bleeding into the muscle rather than around the kidney. Colicky pain similar to that of ureteral colic may develop when a clot is present in the ureter; there may be excruciating, sharp flank pain that radiates to the groin.

All urine that the patient voids is inspected for evidence of bleeding and compared with the prebiopsy specimen and subsequent voiding samples. If bleeding persists, as indicated by an enlarging hematoma, the abdomen should not be palpated or manipulated.
Hematocrit and hemoglobin levels are obtained within 8 hours to assess for changes; decreasing levels may indicate bleeding. Usually, the fluid intake is maintained at 3,000 mL/day unless the patient has renal insufficiency. If bleeding occurs, the patient is prepared for blood component therapy and surgical intervention to control the hemorrhage; surgical drainage or, rarely, nephrectomy (removal of the kidney) may be needed.

**Patient Teaching.** Because hemorrhage can occur up to several days after the biopsy, the patient is instructed to avoid strenuous activities, sports, and heavy lifting for at least 2 weeks. The patient and family are instructed to notify the physician or clinic if any of the following occur: flank pain, hematuria, light-headedness and fainting, rapid pulse, or any other signs and symptoms of bleeding.

**URODYNAMIC TESTS**

Urodynamic tests provide an accurate evaluation of voiding problems, thus assisting in diagnosis. Urodynamic studies are useful in evaluating changes in bladder filling and bladder emptying. Chart 43-4 outlines patient education for all basic urodynamic tests. The following urodynamic test procedures and measurements are the most common and are often performed simultaneously (Albaugh, 1999; Appell, 1999).

**Uroflowmetry**

Uroflowmetry (flow rate) is the record of the volume of urine passing through the urethra per time unit (milliliters per second). The flow rate reflects the combined activity of the detrusor muscle and the bladder neck and the degree of relaxation of the urethral sphincter. Because this test depends on the amount voided, the patient is instructed to arrive for the test with a strong urge to void, but not have an overly full bladder (EMG). When urethral sphincter competency is being evaluated, uroflowmetry is combined with electromyographic measurement of the external urethral sphincter via surface wire or needle electrodes placed at the level of the sphincter, on either side of the urethra. Uroflowmetry is often combined with cystometry, in which case the bladder is filled as the intravesical pressure is being monitored before the voiding phase of the study.

**Cystometry**

A cystometrogram (CMG) is a graphic recording of the pressures in the bladder during bladder filling and emptying. It is the major diagnostic portion of urodynamic testing. During the test, the amount of fluid instilled into the bladder and the patient’s sensations of bladder fullness and urge to void are recorded. These are then compared with the pressures measured in the bladder during bladder emptying. A urethral catheter is connected to a water manometer, and sterile solution of either normal saline or water is allowed to flow into the bladder, usually at the rate of 1 mL/sec. The patient informs the examiner when the first sensation of bladder filling is felt, when mild urgency is noted, and again when the bladder feels full. The degree of bladder filling at these points is recorded. The pressures above the zero level at the symphysis pubis are measured, and the pressures and volumes within the bladder are plotted and recorded. This test measures bladder sensation, compliance of the bladder wall during filling, and functional capacity. It also evaluates any phasic or sharp increases in bladder pressure, which may or may not be associated with incontinence of the infused fluid.

Throughout and at the end of bladder filling, the degree of abdominal pressure against the bladder, which could potentially cause leaking (stress incontinence), is measured. This measurement is referred to as the Valsalva leak-point pressure (VLPP). The terms VLPP and abdominal leak-point pressure can be used interchangeably.

While in a sitting or standing position, the patient is asked to cough or perform a Valsalva maneuver to assess whether urine leaks. Before this test is performed, it is important to determine if the patient is prone to vasovagal reactions and to alert the urodynamicist. A competent sphincter will not allow for any loss of

**Chart 43-4 • PATIENT EDUCATION Before and After Urodynamic Testing**

In preparing the patient for urodynamic testing, the nurse instructs the patient about how urodynamic procedures are performed, what is expected of the patient, and what sensations the patient can expect afterward. The nurse reassures the patient that staff will be present during the procedure, but privacy and comfort will be maintained. Additional information for the patient follows:

- An in-depth interview will be conducted. Questions related to your urologic symptoms and voiding habits will be asked by the staff.
- You will be asked to describe sensations felt during the procedure.
- During the procedure, you might be asked to change positions (for example, from supine to sitting or standing).
- You may be asked to cough or perform the Valsalva maneuver (bear down) during the procedure.
- You will probably need to have one or two urethral catheters inserted so that bladder pressure and bladder filling can be measured. Another catheter may be placed in the rectum or vagina to measure abdominal pressure.
- You may also have electrodes (surface, wire, or needle) placed in the perianal area for electromyography (EMG). This may be uncomfortable initially during insertion and later during position changes.
- Your bladder will be filled through the urethral catheter one or more times during the procedure.
- After the procedure, you may experience urinary frequency, urgency, or dysuria from the urethral catheters. Avoid caffeinated, carbonated, and alcoholic beverages after the procedure because these can further irritate the bladder. These symptoms usually decrease or subside by the day after the procedure.
- You might notice a slight hematuria (blood-tinged urine) right after the procedure (especially in men with benign prostatic hyperplasia). Drinking fluids will help to clear the hematuria.
- If the urinary meatus is irritated, a warm sitz bath may be helpful.
- Be alert for signs of a urinary tract infection after the procedure. Contact your physician if you experience fever, chills, lower back pain, or continued dysuria and hematuria.
- If you receive an antibiotic medication before the procedure, you should continue taking the complete course of medication after the procedure. This is a measure to prevent infection.
urine, even with a full bladder and maneuvers such as a cough, laugh, or position change. When minimal weakness of the urethral sphincter causes a small amount of incontinence (currently considered leakage at or above a bladder pressure of 100 cm H2O), urethral hypermobility is the cause. When leakage occurs with a cough or the Valsalva maneuver at bladder pressures less than 100 cm H2O, intrinsic sphincter deficiency is believed to contribute to the incontinence. During the cystogram portion of the urodynamic study, if any urine leakage is noted when the patient coughs or performs a Valsalva maneuver, regardless of the amount of abdominal force that caused the leaking, a diagnosis of “genuine stress urinary incontinence” is made. The VLPP determines the severity of SUI.

**Urinary Pressure Flow**

Urinary pressure flow is a study that is performed immediately after the filling phase of the CMG and simultaneously with the voiding CMG. Bladder pressure, urine flow, and sphincter electromyography are measured simultaneously. This allows for a detailed picture of voiding function.

**Electromyography**

Electromyography (EMG) involves the placement of electrodes in the pelvic floor musculature or over the area of the anal sphincter to evaluate the neuromuscular function of the lower tract. It is usually performed simultaneously with the CMG.

**Videofluorourodynamic Study**

The videofluorourodynamic study is considered the optimal urodynamic evaluation. This test combines a study of the filling and voiding phases of the CMG and the EMG with a simultaneous visualization of the lower urinary tract via a radiopaque filling agent in place of sterile water or saline. It allows for a complete and detailed assessment of the voiding dysfunction, which may be due in part to anatomic dysfunction.

**Urethral Pressure Profile**

The urethral pressure profile measures the amount of urethral pressure along the length of the urethra needed to maintain continence. Gas or fluid is instilled through a catheter that is withdrawn while the pressures along the urethral wall are obtained.

**Nursing Implications**

Most patients undergoing urologic testing or imaging studies are apprehensive, even those who have had these tests in the past. Patients frequently feel discomfort and embarrassment about such a private and personal function as voiding. Voiding in the presence of others can frequently cause guarding, a natural reflex that inhibits voiding due to situational anxiety. Because the outcomes of these studies determine the plan of care, the nurse must help the patient relax by providing as much privacy and explanation about the procedure as possible.

**NURSING DIAGNOSIS**

Potential nursing diagnoses for the patient undergoing assessment of urinary or renal function include the following:

- Deficient knowledge about the procedures and diagnostic tests
- Acute pain related to renal infection, edema, obstruction, or bleeding along the urinary tract, or to invasive diagnostic procedures
- Fear related to possible diagnosis of serious illness, altered renal function, and embarrassment secondary to discussion of urinary function, and exposure and invasion of genitalia

**PLANNING, IMPLEMENTATION, AND EVALUATION**

The goals, nursing interventions and rationale, and expected outcomes are discussed in greater detail in the Plan of Nursing Care. Patient and family education is essential to help the patient understand the purpose of the procedure and what to expect before, during, and after it. Pertinent home care considerations can be discussed at this time.

**Promoting Home and Community-Based Care**

**TEACHING PATIENTS SELF-CARE**

Many procedures and tests used to evaluate upper and lower urinary tract function are carried out in outpatient or short-procedure settings. Therefore, family members or other caregivers in the home may be called upon to provide postprocedural care. They need clear explanations about the procedures and tests, how to prepare for them, and what precautions, if any, need to be taken afterward. The patient and family members are provided with verbal and written explanations about monitoring that may be necessary at home and are instructed about steps to take if complications occur.

**CONTINUING CARE**

Follow-up telephone calls made to the patient and family at home provide an opportunity for them to ask questions and to report on the patient’s status. Teaching is reinforced, and the patient is reminded of the importance of keeping follow-up appointments with primary health care providers.

**Critical Thinking Exercises**

1. Following the removal of an indwelling catheter 2 days after a complete abdominal hysterectomy, your patient complains of abdominal pain. An abdominal examination confirms a distended bladder on visual observation, dullness to percussion over the suprapubic area, and pain with light palpation to this area. You confirm your suspicions of acute urine retention when a review of the urine output over the past 12 hours shows no output and the patient confirms that she has not voided since the catheter was removed. What should be your next course of action? Review the possible causes, and describe the actions you could take and the rationale for each action.

2. A 65-year-old man with newly diagnosed type 2 diabetes comes to the primary care clinic for his quarterly lab work and urinalysis. He states that he has been following the dietitian’s recommendations for his diabetic diet. Results of a urinalysis demonstrate a protein level greater than 250 mg/dL and a glucose level greater than 400 mg/dL. Explain the appropriate patient education in regard to these findings in relation to the management of his diabetes.
## Plan of Nursing Care

### Care of the Patient Undergoing Diagnostic Testing of the Renal-Urologic System

Management of Patients With Upper or Lower Urinary Tract Dysfunction

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

1. Explain the different types of urinary incontinence and their causes.
2. Compare and contrast urinary retention and urinary incontinence in terms of their clinical manifestations, complications, and medical and nursing management.
3. Describe the sequence of events leading to urinary tract infection in a patient with an indwelling urinary catheter.
4. Outline the principles of management of a patient with an indwelling urinary catheter.
5. Compare and contrast hemodialysis and peritoneal dialysis in terms of underlying principles, procedures, complications, and nursing considerations.
6. Describe nursing management of the hospitalized dialysis patient.
7. Use the nursing process as a framework for care of patients undergoing kidney surgery.
Patients with disorders of the upper or lower urinary tract often exhibit similar problems, regardless of the underlying disorder. This chapter provides an overview of common problems that these patients experience, such as fluid and electrolyte imbalances and dysfunctional voiding patterns. Interdisciplinary medical and surgical management strategies (eg, catheterization, dialysis, and surgery) for various urologic diseases and disorders are also discussed.

**Fluid and Electrolyte Imbalances in Renal Disorders**

Patients with renal disorders commonly experience fluid and electrolyte imbalances and require astute assessment and close monitoring for signs of potential problems. The fluid intake and output record, a key monitoring tool, is used to document important fluid parameters, including the amount of fluid taken in (orally or parenterally), the volume of urine excreted, and other fluid losses (diarrhea, vomiting, diaphoresis).

These records and changes in the patient’s weight are essential for determining the daily fluid allowance and indicating signs of fluid overload or deficit. The patient whose fluid intake exceeds the ability of the kidneys to excrete fluid is said to have a fluid overload. If fluid intake is inadequate, the patient is said to be volume-depleted and may show signs and symptoms of fluid volume deficit.

**Clinical Manifestations**

The signs and symptoms of common fluid and electrolyte disturbances that can occur in patients with renal disease are listed in Table 44-1, as are general management strategies. The nurse should continually assess, monitor, and inform appropriate members of the health care team if the patient exhibits any of these signs. Management strategies for fluid and electrolyte disturbances in renal disease are discussed in greater depth later in this chapter (see also Chap. 14).

Dysfunctional Voiding Patterns

Dysfunctional voiding presents in the form of urinary incontinence or urine retention. Urinary incontinence is the unplanned loss of urine that is sufficient to be considered a problem. Urinary continence relies on intact urinary, neurologic, and musculoskeletal systems. Continence is maintained via a complex communication system of suprasacral, sacral, and local nerve-mediated loops of information, all of which must be functioning efficiently and synergistically. Any break in these loops of communication (for example, an upper or lower neuron lesion, spinal stenosis, or bladder outlet obstruction) can cause some degree of urinary dysfunction. Depending on the location of the insult, both incontinence and incomplete bladder emptying can occur. Anatomic integrity of the upper and lower urinary system must be intact; otherwise, urine extravasation into the peritoneal or perivesical cavity (as seen in acute trauma) or extravesical incontinence (as seen in some forms of congenital malformations) will occur. Genitourinary fistula formation between the bladder wall and other areas, such as the vagina, will result in extraurethral incontinence. The etiology of dysfunctional voiding can be congenital or acquired in adulthood. Each is reviewed separately.

CONGENITAL VOIDING DYSFUNCTION

Congenital anomalies usually result in voiding dysfunction early in life and are usually partially or completely surgically corrected. When voiding dysfunction occurs in adults, it may affect only the lower urinary system (e.g., the bladder and urethra); when voiding dysfunction occurs in children, it commonly involves damage to the upper urinary system (i.e., the ureters and kidneys) as well. Many congenital anomalies are discovered early in utero because of prenatal care measures such as ultrasound. The urinary system begins developing days after conception, and anomalies can be seen on a sonogram as early as 20 weeks. Depending on the anomaly, intratubarine surgery may be performed on the fetus. Because the urinary system may be only one of several organ systems that are abnormal due to genetic disorders, any defects not noted during gestation should be immediately apparent at birth. Such anomalies include renal agenesis (complete absence of one or both kidneys), ectopic ureter, and Eagle-Barrett syndrome (also known as prune-belly syndrome), with exstrophy of the bladder. On the other hand, voiding dysfunction can be discovered insidiously (for example, during toilet training). At times congenital anomalies, such as posterior urethral valves, typically seen only in males, may escape detection until early adolescence or adulthood, when the voiding dysfunction or its sequelae cause the individual to seek urologic evaluation. Although pediatric in nature, these disorders may affect urinary tract function when the patient becomes an adult.

ADULT VOIDING DYSFUNCTION

Both neurogenic and non-neurogenic disorders can cause adult voiding dysfunction (Table 44-2). The micturition (voiding) process involves several highly coordinated neurologic responses that mediate bladder function. A functional urinary system allows for appropriate bladder filling and complete bladder emptying (see Chap. 43). If voiding dysfunction goes undetected and un-

treated, the upper urinary system may be compromised. Chronic incomplete bladder emptying from poor detrusor pressure results in recurrent bladder infection. Incomplete bladder emptying due to bladder outlet obstruction (such as benign prostatic hyperplasia), causing high-pressure detrusor contractions, can result in hydronephrosis from the high detrusor pressure that radiates up the ureters to the renal pelves.

**URINARY INCONTINENCE**

More than 17 million adults in the United States are estimated to have urinary incontinence, with most of them experiencing overactive bladder syndrome, making this disorder more prevalent than diabetes or ulcer disease. Despite widespread media coverage, urinary incontinence remains underdiagnosed and underreported. Patients may be too embarrassed to seek help, causing them to ignore or conceal symptoms. Many patients resort to using absorbent pads or other devices without having their condition properly diagnosed and treated. Health care providers must be alert to subtle cues of urinary incontinence and stay informed about current management strategies.

The costs of care for patients with urinary incontinence are not limited to the dollars spent for absorbent products, medications, and surgical or nonsurgical treatment modalities. The psychosocial costs of urinary incontinence are also significant: embarrassment, loss of self-esteem, and social isolation are common outcomes. Urinary incontinence in elderly patients often decreases their ability to maintain an independent lifestyle. This increases dependence on caregivers and often leads to institutionalization.

Urinary incontinence affects people of all ages but is particularly common among the elderly. It has been reported that more than half of all nursing home residents have urinary incontinence. Although urinary incontinence is not a normal consequence of aging, age-related changes in the urinary tract predispose the older person to incontinence.

Although urinary incontinence is commonly regarded as a condition that occurs in older multiporous women, it is also common in young nulliporous women, especially during vigorous high-impact activity. Age, gender, and number of vaginal deliveries are established risk factors (Chart 44-1); they explain, in part, the increased incidence in women. Urinary incontinence is a symptom with many possible causes.

**Clinical Manifestations: Types of Incontinence**

*Stress incontinence* is the involuntary loss of urine through an intact urethra as a result of a sudden increase in intra-abdominal pressure (sneezing, coughing, or changing position). It predominately affects women who have had vaginal deliveries and is thought to be the result of decreasing ligament and pelvic floor support of the urethra and decreasing or absent estrogen levels within the urethral walls and bladder base. In men, stress incontinence is often experienced after a radical prostatectomy for prostate cancer because of the loss of urethral compression that the prostate had supplied before the surgery, and possibly bladder wall irritability (Reilly, 2001; Sueppel et al., 2001) (see Nursing Research Profile 44-1).

*urge incontinence* is the involuntary loss of urine associated with a strong urge to void that cannot be suppressed. The patient is aware of the need to void but is unable to reach a toilet in time. An uninhibited detrusor contraction is the precipitating factor. This can occur in a patient with neurologic dysfunction that impairs inhibition of bladder contraction or in a patient without overt neurologic dysfunction (Chancellor, 1999).

*Reflex incontinence* is the involuntary loss of urine due to hyperreflexia in the absence of normal sensations usually associated with voiding. This commonly occurs in patients with spinal cord injury because they have neither neurologically mediated motor control of the detrusor nor sensory awareness of the need to void.

*Overflow incontinence* is the involuntary loss of urine associated with overdistention of the bladder. Such overdistention results from the bladder’s inability to empty normally, despite frequent urine loss. Both neurologic abnormalities (eg, spinal cord lesions) and factors that obstruct the outflow of urine (eg, tumors, strictures, and prostatic hyperplasia) can cause overflow incontinence (Reilly, 2001).

Functional incontinence refers to those instances in which lower urinary tract function is intact but other factors, such as severe cognitive impairment (eg, Alzheimer’s dementia), make it difficult for the patient to identify the need to void or physical impairments make it difficult or impossible for the patient to reach the toilet in time for voiding.

Iatrogenic incontinence refers to the involuntary loss of urine due to extrinsic medical factors, predominantly medications. One such example is the use of alpha-adrenergic agents to lower blood pressure. In some individuals with an intact urinary system, these agents adversely affect the alpha receptors responsible for bladder neck closing pressure; the bladder neck relaxes to the point of incontinence with a minimal increase in intra-abdominal pressure, thus mimicking stress incontinence. As soon as the medication is discontinued, the apparent incontinence resolves (Reilly, 2001).

Some patients have several types of urinary incontinence. This mixed incontinence is usually a combination of stress and urge incontinence.

Only with appropriate recognition of the problem, assessment, and referral for diagnostic evaluation and treatment can the outcome of incontinence be determined. All people with incontinence should be considered for evaluation and treatment.

**Assessment and Diagnostic Findings**

Once incontinence is recognized, a thorough history is necessary. This includes a detailed description of the problem and a history of medication use. The patient’s voiding history, a diary of fluid intake and output, and bedside tests (ie, *residual urine*, stress maneuvers) may be used to help determine the type of urinary
incontinence involved. Extensive urodynamic tests may be performed; see Chapter 43. Urinalysis and urine culture are performed to identify hematuria (from infection, cancer, or a kidney stone), glycosuria (causes polyuria), pyuria, and bacteriuria (bacteria in the urine), all of which may identify transient causes of urinary incontinence.

Management depends on the type of urinary incontinence and its causes. Urinary incontinence may be transient or reversible (Chart 44-2), provided that the underlying cause is successfully treated and the voiding pattern reverts to normal. Management of urinary incontinence not considered transient or reversible falls into three categories: pharmacologic, surgical, and behavioral.

Gerontologic Considerations

Many older individuals experience transient episodes of incontinence that tend to be abrupt in onset. When this occurs, the nurse should question the patient, as well as the family if possible, about the onset of symptoms and any signs or symptoms of a change in other organ systems.

Acute urinary tract infection, infection elsewhere in the body, constipation, decreased fluid intake, a change in a chronic disease pattern, such as elevated blood glucose levels in patients with diabetes or decreased estrogen levels in menopausal women, can provoke the onset of urinary incontinence. If the cause is identified and modified or eliminated early at the onset of incontinence, the incontinence itself may be eliminated. Although the older bladder is more vulnerable to unstable detrusor activity, age alone is not a risk factor for urinary incontinence (Suchinski et al., 1999).

Medical Management

Treatment of urinary incontinence depends on the underlying cause. Before appropriate treatment can be initiated, however, the problem and the cause must be identified.

BEHAVIORAL THERAPY

Behavioral therapies are always the first choice to decrease or eliminate urinary incontinence. In using these techniques, clinicians help patients avoid potential adverse effects of pharmacologic or surgical interventions (AHCPR, 1996; Roberts, 2001) (Chart 44-3).

PHARMACOLOGIC THERAPY

Pharmacologic therapy works best when used as an adjunct to behavioral interventions. Anticholinergic agents (oxybutynin [Ditropan], dicyclomine [Antispas]) inhibit bladder contraction and are considered first-line medications for urge incontinence. Several tricyclic antidepressant medications (imipramine, doxepin, desipramine, and nortriptyline) also decrease bladder contractions as well as increase bladder neck resistance. Stress incontinence may be treated using pseudoephedrine (eg, Sudafed). Estrogen (taken orally, transdermally, or topically) has been shown to be beneficial for all types of urinary incontinence. Estrogen decreases obstruction to urine flow by restoring the mucosal, vascular, and muscular integrity of the urethra.

Gerontologic Considerations

Elderly individuals may experience cognitive decline when taking short-acting anticholinergic medications. The long-acting forms of anticholinergic medications such as oxybutynin (Ditropan XL)

Nursing Research Profile 44-1

Urinary Incontinence Following Prostatectomy

Purpose

Urinary incontinence is debilitating for some men after radical prostatectomy. Previous research shows that men with preoperative symptoms of urinary urgency, frequency, and nocturia are more likely to have persistent incontinence than men without preoperative symptoms. The objective of this study was to evaluate urine loss, quality of life, and urodynamic findings in men with persistent urinary incontinence 12 months after radical prostatectomy.

Study Sample and Design

One hundred eighty men from a previous study on quality of life (QOL) and treatment for post-prostatectomy incontinence were asked to participate. Sixty-three men who were still incontinent participated in the study and were asked to complete a 24-hour pad test, a frequency/volume chart, and a QOL questionnaire at 2, 3, 6, and 8 months after radical prostatectomy. Persistent incontinence was defined as more than 10 g of urine loss on a 24-hour pad test at 8 months after surgery. Of the original 63 men, 21 were identified as still being incontinent. A second researcher then contacted these men for enrollment for video urodynamic testing. Sixteen of the 21 agreed to participate and underwent video urodynamic testing.

Findings

Four of the 16 men in the final sample reported preoperative urinary urgency, frequency, and nocturia. These 4 as well as 3 others (7), demonstrated objective evidence of overactive bladder (detrusor instability) on urodynamics. Four of these 7 had demonstrable stress incontinence as well (mixed incontinence). One other study participant demonstrated stress incontinence without associated detrusor instability. Although the retrospective nature of the questionnaire is a limitation of the study, the findings suggest that preoperative symptoms may be a risk factor for postoperative incontinence.

Nursing Implications

Men who have postoperative symptoms of stress incontinence may well have unrecognized detrusor dysfunction that, if recognized, could be treated, although symptoms of stress incontinence may persist. Preoperative identification of men with detrusor dysfunction could result in an altered postoperative plan of care to increase the overall level of continence and improved quality of life.
### Behavioral Interventions for Urinary Incontinence

Behavioral strategies are largely carried out, coordinated, and monitored by the nurse. These interventions may or may not be augmented by the use of medications.

#### Fluid Management
One of the most common approaches is fluid management because adequate daily fluid intake of approximately 50 to 60 ounces (1,500 to 1,600 mL), taken as small increments between breakfast and the evening meal, helps to reduce urinary urgency related to concentrated urine production, decreases the risk of urinary tract infection, and maintains bowel functioning.

Constipation, resulting from inadequate daily fluid intake, can increase urinary urgency and/or urine retention. The best fluid is water. Fluids containing caffeine, carbonation, alcohol, or artificial sweetener should be avoided because they irritate the bladder wall, thus resulting in urinary urgency. Some individuals who have coexisting medical diagnoses, such as heart failure or end-stage renal disease, need to discuss their daily fluid limit with their primary health care provider.

#### Standardized Voiding Frequency
After establishing a patient’s natural voiding and urinary incontinence tendencies, voiding on a schedule can be very effective in both cognitively intact and cognitively impaired patients, although cognitively impaired patients require assistance with this technique from nursing personnel or family members. The object is to purposely empty the bladder before the bladder reaches the critical volume that would cause an urge or stress incontinence episode. This approach involves the following:

- **Timed voiding** involves establishing a set voiding frequency (such as every 2 hours if incontinent episodes tend to occur 2 or more hours after voiding). The individual chooses to “void by the clock” at the given interval while awake, rather than wait until a voiding urge occurs.
- **Prompted voiding** is timed voiding that is carried out by staff or family members when the individual has cognitive difficulties that make it difficult to remember to void at set intervals. The caregiver checks the patient to assess if he or she has remained dry and, if so, assists the patient to use the bathroom while providing positive reinforcement for remaining dry.
- **Habit retraining** is timed voiding at an interval that is more frequent than the individual would usually choose. This technique helps to restore the sensation of the need to void in individuals who are experiencing diminished sensation of bladder filling due to various medical conditions such as a mild cerebrovascular accident (CVA).
- **Bladder retraining**, also known as “bladder drill,” incorporates a timed voiding schedule and urinary urge inhibition exercises to inhibit voiding, or leaking urine, in an attempt to remain dry for a set time. When the first timing interval is easily reached on a consistent basis without urinary urgency or incontinence, a new voiding interval, usually 10 to 15 minutes beyond the last, is established. Again, the individual practices urge inhibition exercises to delay voiding or avoid incontinence until the next preset interval arrives. When an acceptable voiding interval is reached, the patient continues that timed voiding sequence throughout the day.

#### Pelvic Muscle Exercise (PME)

Also known as Kegel exercises, PME aims to strengthen the voluntary muscles that assist in bladder and bowel continence in both men and women. Research shows that written and/or verbal instruction alone is usually inadequate to teach an individual how to identify and strengthen the pelvic floor for sufficient bladder and bowel control (Sueppel, et al, 2001; Joseph & Chang, 2000). Biofeedback-assisted PME uses either electromyography or manometry to help the individual identify the pelvic muscles as he or she attempts to learn which muscle group is involved when performing PME. The biofeedback method also allows assessment of the strength of this muscle area while the exercise is taking place (AHCPR, 1996).

PME involves gently tightening the same muscles used to stop flatus or the stream of urine for 5- to 10-second increments, followed by 10-second resting phases. To be effective, these exercises need to be performed 2 or 3 times a day for at least 6 weeks. Depending on the strength of the pelvic musculature when initially evaluated, anywhere from 10 to 30 repetitions of PME are prescribed at each session. Elderly patients may need to exercise for an even longer time to strengthen the pelvic floor muscles. Pelvic muscle exercises are helpful for women with stress, urge, or mixed incontinence and for men who have undergone prostate surgery.

#### Vaginal Cone Retention Exercises

Vaginal cone retention exercises are an adjunct to the Kegel exercises. Vaginal cones of varying weight are inserted intravaginally twice a day. The patient tries to retain the cone for 15 minutes by contracting the pelvic muscles.

#### Transvaginal or Transrectal Electrical Stimulation

Commonly used to treat urinary incontinence, electrical stimulation is known to elicit a passive contraction of the pelvic floor musculature, thus re-educating these muscles to provide enhanced levels of continence. This modality is often used with biofeedback-assisted pelvic muscle exercise training and voiding schedules. At high frequencies, it is effective for stress incontinence. At low frequencies, electrical stimulation can also relieve symptoms of urinary urgency, frequency, and urge incontinence. Intermediate ranges are used for mixed incontinence (AHCPR, 1996; Bernier & Davila, 2000).

#### Neuromodulation

Neuromodulation via transvaginal or transrectal nerve stimulation of the pelvic floor inhibits detrusor overactivity and hypersensory bladder signals and strengthens weak sphincter muscles.

---

**Chapter 44** Management of Patients With Upper or Lower Urinary Tract Dysfunction

and tolterodine (Detrol LA) have a significantly lower incidence of adverse effects in all populations, including the elderly (Roberts, 2001).

**SURGICAL MANAGEMENT**

Surgical correction may be indicated in patients who have not achieved continence using behavioral and pharmacological therapy. Surgical options vary according to the underlying anatomy and the physiologic problem. Most procedures involve lifting and stabilizing the bladder or urethra to restore the normal urethrovaginal angle or to lengthen the urethra.

Women with stress incontinence may have an anterior vaginal repair, retropubic suspension, or needle suspension to reposition the urethra. Procedures to compress the urethra and increase resistance to urine flow include sling procedures and placement of periurethral bulking agents such as artificial collagen.

Periurethral bulking is a semipermanent procedure in which small amounts of artificial collagen are placed within the walls of the urethra to enhance the closing pressure of the urethra. This procedure takes only 10 to 20 minutes and may be performed under local anesthesia or moderate sedation. A cystoscope is inserted into the urethra. An instrument is inserted through the cystoscope to deliver a small amount of collagen into the urethral wall at locations selected by the urologist. The patient is usually discharged home after voiding. There are no restrictions following the procedure, although occasionally more than one collagen
bulking session may be necessary if the initial procedure did not halt the stress urinary incontinence. Collagen placement anywhere in the body is considered semipermanent because its durability averages between 12 and 24 months, until the body absorbs the material. Periurethral bulking with collagen offers an alternative to surgery, as in a frail, elderly individual. It is also an option for individuals who are seeking help with stress urinary incontinence who prefer to avoid surgery and who do not have access to biofeedback and electrical stimulation.

A modified artificial sphincter that uses a silicone-rubber balloon as a self-regulating pressure mechanism can be used to close the urethra. Electronic stimulation of the pelvic floor by means of a miniature pulse generator with electrodes mounted on an intra-anal plug is another method of controlling stress incontinence.

Men with overflow and stress incontinence may undergo a transurethral resection to relieve symptoms of prostatic enlargement. An artificial sphincter can be used after prostatic surgery for sphincter incompetence (Fig. 44-1). After surgery, periurethral bulking agents can be injected into the periurethral area to increase compression of the urethra.

Nursing Management

Nursing management is based on the premise that incontinence is not inevitable with illness or aging and that it is often reversible and treatable. The nursing interventions are determined in part by the type of treatment that is undertaken. For behavioral therapy to be effective, the nurse must provide support and encouragement, because it is easy for the patient to become discouraged if therapy does not quickly improve the level of continence. Patient teaching regarding the bladder program is important and should be provided verbally and in writing (Chart 44-4). The patient is assisted to develop and use a log or diary to record timing of Kegel exercises, changes in bladder function with treatment, and episodes of incontinence.

If pharmacologic treatment is used, its purpose is explained to the patient and family. If surgical correction is undertaken, the procedure and its desired outcomes are described to the patient and family. Follow-up contact with the patient enables the nurse to answer the patient’s questions and to provide reinforcement and encouragement. Patients who have mixed incontinence (both stress and urge incontinence) need to understand that anticholinergic and antispasmodic agents can help decrease urinary urgency and frequency and urge incontinence, but they do not decrease the urinary incontinence related to stress incontinence.

Urinary Retention

Urinary retention is the inability to empty the bladder completely during attempts to void. Chronic urine retention often leads to overflow incontinence (from the pressure of the retained urine in the bladder). Residual urine is urine that remains in the bladder after voiding. In a healthy adult younger than age 60, 50 to 100 mL of residual urine may remain after each void because of the decreased contractility of the detrusor muscle. Urinary retention can occur postoperatively in any patient, particularly if the surgery affected the perineal or anal regions and resulted in reflex spasm of the sphincters. General anesthesia reduces bladder muscle innervation and suppresses the urge to void, impeding bladder emptying (Gray, 2000a, 2000b).

Pathophysiology

Urinary retention may result from diabetes, prostatic enlargement, urethral pathology (infection, tumor, calculus), trauma (pelvic injuries), pregnancy, or neurologic disorders such as cerebrovascular accident, spinal cord injury, multiple sclerosis, or Parkinson’s disease.

Some medications cause urinary retention, either by inhibiting bladder contractility or by increasing bladder outlet resistance. Medications that cause retention by inhibiting bladder contractility include anticholinergic agents (atropine sulfate, dicyclomine hydrochloride [Antispas, Bentyl]), antispasmodic agents (oxybutynin chloride [Ditropan], belladonna, and opioid suppositories), and tricyclic antidepressant medications (imipramine [Tofranil], doxepin [Sinequan]). Medications that cause urine retention by increasing bladder outlet resistance include alpha-adrenergic agents (ephrine sulfate, pseudoephedrine), beta-adrenergic blockers (propranolol), and estrogens.
Assessment and Diagnostic Findings

The assessment of a patient for urinary retention is multifaceted because the signs and symptoms may be easily overlooked. The following questions serve as a guide in assessment:

- What was the time of the last voiding, and how much urine was excreted?
- Is the patient voiding small amounts of urine frequently?
- Is the patient dribbling urine?
- Does the patient complain of pain or discomfort in the lower abdomen? (Discomfort may be relatively mild if the bladder distends slowly.)
- Is the pelvic area rounded and swollen (could indicate urine retention and a distended bladder)?
- Does percussion of the suprapubic region elicit dullness (possibly indicating urine retention and a distended bladder)?
- Are other indicators of urinary retention present, such as restlessness and agitation?
- Does a postvoid bladder ultrasound test reveal residual urine?

The patient may verbalize an awareness of bladder fullness and a sensation of incomplete bladder emptying. The nurse also assesses the patient for signs and symptoms of urinary tract infection, such as hematuria and dysuria. A series of urodynamic studies, described in Chapter 43, may be performed to identify the type of bladder dysfunction and to aid in determining appropriate treatment. The patient may complete a voiding diary to provide a written record of the amount of urine voided and the frequency of voiding.

Postvoid residual urine can be measured accurately without the need for postvoid straight catheterization using a portable ultrasound bladder scanner (see Nursing Research Profile 44-2). The scanner is operated by gently pressing a wand-like scan head that detects fluid over the bladder. If the scanner detects more than 100 mL of urine after a patient voids, a postvoid catheterization should be considered to reduce the risks of urinary tract infection and bladder overdistention (Phillips, 2000; Schott-Baer & Reaume, 2001).

Complications

Urinary retention can lead to chronic infection. Infections that are unresolved predispose the patient to calculi, pyelonephritis, and sepsis. The kidney may also eventually deteriorate if large volumes of urine are retained, causing backward pressure on the upper urinary tract. In addition, urine leakage can lead to perineal skin breakdown, especially if regular hygiene measures are neglected.

Nursing Management

Management strategies are instituted to prevent overdistention of the bladder and to treat infection or correct obstruction. Many problems, however, can be prevented with careful nursing assessment and appropriate nursing interventions. The nurse should explain why normal voiding is not occurring and should monitor urine output closely. The nurse should also provide reassurance about the temporary nature of retention and successful management strategies.

PROMOTING NORMAL URINARY ELIMINATION

Nursing measures to encourage voiding include providing privacy, ensuring an environment and a position conducive to voiding, and assisting the patient with the use of the bathroom or commode, rather than a bedpan, to provide a more natural setting for voiding. The male patient may stand beside the bed while using the urinal; most men find this position more comfortable and natural.

Additional measures include applying warmth to relax the sphincters (ie, sitz baths, warm compresses to the perineum, showers), giving the patient hot tea, and offering encouragement and reassurance. Simple trigger techniques, such as turning on the water faucet while the patient is trying to void, may also be used. Other examples of trigger techniques are stroking the abdomen or inner thighs, tapping above the pubic area, and dipping the patient’s hands in warm water. A combination of techniques may be necessary to initiate voiding.

After surgery, the prescribed analgesic should be administered because pain in the incisional area can make voiding difficult.

PROMOTING URINARY ELIMINATION

When the patient cannot void, catheterization is used to prevent overdistention of the bladder (see later discussion of neurogenic bladder and catheterization). In the case of prostatic obstruction, attempts at catheterization (by the urologist) may not be successful,
requiring insertion of a suprapubic catheter. After urinary drainage is restored, bladder retraining is initiated for the patient who cannot void spontaneously.

**PROMOTING HOME AND COMMUNITY-BASED CARE**

Modifying the home environment is a simple and effective way to treat urinary incontinence. In adapting the home environment to provide easy, safe access to the bathroom, the patient may need to remove barriers, such as throw rugs or other objects, from the route. Other modifications that the nurse may recommend include installing support bars in the bathroom and placing a bedpan or urinal within easy reach. Leaving a light on in the bedroom and bathroom and wearing clothing that is easy to remove when using the toilet are other recommendations (see Chart 44-4).

**Gerontologic Considerations**

If nurses and other health care providers accept incontinence as an inevitable part of illness or aging or consider it irreversible and untreatable at any age, it cannot be treated successfully. Collaborative, interdisciplinary efforts are essential in assessing and effectively treating urinary incontinence.

**NEUROGENIC BLADDER**

**Neurogenic bladder** is a dysfunction that results from a lesion of the nervous system. It may be caused by spinal cord injury, spinal tumor, herniated vertebral disk, multiple sclerosis, congenital anomalies (spina bifida or myelomeningocele), infection, or diabetes mellitus.

**Pathophysiology**

The two types of neurogenic bladder are spastic (or reflex) bladder and flaccid bladder. Spastic bladder is the more common type and is caused by any spinal cord lesion above the voiding reflex arc (upper motor neuron lesion). The result is a loss of conscious sensation and cerebral motor control. A spastic bladder empties on reflex, with minimal or no controlling influence to regulate its activity.

Flaccid bladder is caused by a lower motor neuron lesion, commonly resulting from trauma. This form of neurogenic bladder has increasingly been recognized as a problem in patients with diabetes mellitus. The bladder continues to fill and becomes greatly distended, and overflow incontinence occurs. The bladder muscle does not contract forcefully at any time. Because sensory loss may accompany a flaccid bladder, the patient feels no discomfort.

**Assessment and Diagnostic Findings**

Evaluation for neurogenic bladder involves measurement of fluid intake, urine output, and residual urine volume; urinalysis; and assessment of sensory awareness of bladder fullness and degree of motor control. Comprehensive urodynamic studies are also performed.

**Complications**

The most common complication of neurogenic bladder is infection resulting from urinary stasis and catheterization. Urolithiasis (stones in the urinary tract) may develop from urinary stasis, infection, or demineralization of bone from prolonged immobility. Renal failure can also occur from vesicoureteral reflux (backward flow of retained urine from the bladder into the ureters) with eventual hydronephrosis (dilation of the pelvis of the kidney resulting from obstruction to the flow of urine) and atrophy of the kidney. Indeed, renal failure is the major cause of death of patients with neurologic impairment of the bladder.

**Medical Management**

The problems resulting from neurogenic bladder disorders vary considerably from patient to patient and are a major challenge to the health care team. There are several long-term objectives appropriate for all types of neurogenic bladders:

- Preventing overdistention of the bladder
- Emptying the bladder regularly and completely
- Preventing overdistention of the bladder
- Preventing overdistention of the bladder

Specific interventions include continuous, intermittent, or self-catheterization (discussed later in this chapter), use of an external condom-type catheter, a diet low in calcium (to prevent calculi), and encouragement of mobility and ambulation. A liberal fluid intake is encouraged to reduce the urinary bacterial count, reduce stasis, decrease the concentration of calcium in the urine, and minimize the precipitation of urinary crystals and subsequent stone formation.

To further enhance bladder emptying of a flaccid bladder, the individual may try “double voiding.” After each voiding, the individual remains on the toilet, relaxes for 1 to 2 minutes, and then attempts to void again in an effort to further empty the bladder. This can be effective in patients with disorders characterized by neurogenic bladder (eg, multiple sclerosis) (Halper, 1998).

Use of timed, or habit, voiding is also considered. For example, a 2-hour voiding schedule may be established to prevent overdistention. A bladder retraining program may be effective in treating a spastic bladder or urine retention (Davies et al., 2000; Joseph, 1999).

**Pharmacologic Therapy**

Parasympathomimetic medications, such as bethanechol (Urecholine), may help to increase the contraction of the detrusor muscle.

**Surgical Management**

In some cases, surgery may be carried out to correct bladder neck contractures or vesicoureteral reflux or to perform some type of urinary diversion procedure.

**Catheterization**

In patients with a urologic disorder or with marginal kidney function, care must be taken to ensure that urinary drainage is adequate and that kidney function is preserved. When urine cannot be eliminated naturally and must be drained artificially, catheters may be inserted directly into the bladder, the ureter, or the renal pelvis. Catheters vary in size, shape, length, material, and configuration. The type of catheter used depends on its purpose.

**NURSING ALERT** Latex catheters and drainage systems must not be used with patients who have known or possible latex allergy.

Catheterization is performed to achieve the following:

- Relieve urinary tract obstruction
- Assist with postoperative drainage in urologic and other surgeries
Suprapubic Catheterization. Suprapubic catheterization allows bladder drainage by inserting a catheter or tube into the bladder through a suprapubic (above the pubis) incision or puncture (Fig. 44-2). It may be a temporary measure to divert the flow of urine from the urethra when the urethral route is impassable (because of injuries, strictures, prostatic obstruction), after gynecologic or other abdominal surgery when bladder dysfunction is likely to occur, and occasionally after pelvic fractures. Suprapubic catheters may also be used on a long-term basis for women with urethral destruction secondary to long-term indwelling urethral catheters (Addison, 1999a, 1999b).

For insertion of the suprapubic catheter, the patient is placed in a supine position and the bladder distended by administering oral or intravenous fluids or by instilling sterile saline solution into the bladder through a urethral catheter. These measures make it easier to locate the bladder. The suprapubic area is prepared as for surgery and the puncture site located about 5 cm (2 in) above the symphysis pubis. The bladder is entered through an incision or through a puncture made by a small trocar (pointed instrument). The catheter or suprapublic drainage tube is threaded into the bladder and secured with sutures or tape; the area around the catheter is covered with a sterile dressing. The catheter is connected to a sterile closed drainage system, and the tubing is secured to prevent tension on the catheter.

Suprapubic bladder drainage may be maintained continuously for several weeks. When the patient’s ability to void is to be tested, the catheter is clamped for 4 hours, during which time the patient attempts to void. After the patient voids, the catheter is unclamped, and the residual urine (the amount of urine remaining) is measured. If the amount of residual urine is less than 100 mL on two separate occasions (morning and evening), the catheter is usually removed. If the patient complains of pain or discomfort, however, the suprapubic catheter is usually left in place until the patient can void successfully. When a suprapubic catheter remains in place indefinitely, it is changed regularly at 6- to 12-week intervals (Gujral et al., 1999).
Suprapubic drainage offers certain advantages. Patients can usually void sooner after surgery than those with urethral catheters, and they may be more comfortable. The catheter allows greater mobility, permits measurement of residual urine without urethral instrumentation, and presents less risk of bladder infection. The suprapubic catheter is removed when it is no longer necessary, and a sterile dressing is placed over the site.

The patient requires liberal amounts of fluid to prevent encrustation around the catheter. Other potential problems include the formation of bladder stones, acute and chronic infections, and problems collecting urine. An enterostomal therapist may be consulted to assist the patient and family in selecting the most suitable urine collection system and to teach them about its use and care.

**Nursing Management During Catheterization**

**ASSESSING THE PATIENT AND THE SYSTEM**

For patients with indwelling catheters, the nurse assesses the drainage system to ensure that it provides adequate urinary drainage. The color, odor, and volume of urine are also monitored. An accurate record of fluid intake and urine output provides essential information about the adequacy of renal function and urinary drainage.

The nurse observes the catheter to make sure that it is properly anchored, to prevent pressure on the urethra at the penoscrotal junction in male patients, and to prevent tension and traction on the bladder in both male and female patients.

Patients at high risk for urinary tract infection from catheterization need to be identified and monitored carefully. These include women, older adults, and patients who are debilitated, malnourished, chronically ill, immunosuppressed, or diabetic. They are observed for signs and symptoms of urinary tract infection: cloudy malodorous urine, hematuria, fever, chills, anorexia, and malaise. The area around the urethral orifice is observed for drainage and excoriation. Urine cultures provide the most accurate means of assessing a patient for infection.

Bladder ultrasonography can be used for noninvasive measurement of bladder volume. A portable bladder scan can be performed to assess the volume of urine in the bladder, the degree of bladder emptying, and therefore the need for catheterization (Phillips, 2000; Schott-Baer & Reaume, 2001).

**ASSESSING FOR AGE-RELATED COMPLICATIONS**

Elderly patients with an indwelling catheter may not exhibit the typical signs and symptoms of infection. Therefore, any subtle change in physical condition or mental status must be considered a possible indication of infection and promptly investigated because sepsis may occur before the infection is diagnosed. Figure 44-3 summarizes the sequence of events leading to infection and leakage of urine that often follow long-term use of an indwelling catheter in elderly patients.

**PREVENTING INFECTION**

Certain principles of care are essential to prevent infection in patients with a closed urinary drainage system (Chart 44-5). The catheter is a foreign body in the urethra and produces a reaction in the urethral mucosa with some urethral discharge. Vigorous cleaning of the meatus while the catheter is in place is discouraged, however, because the cleaning action can move the catheter to and fro, increasing the risk of infection. To remove obvious encrustations from the external catheter surface, the area can be washed gently with soap during the daily bath. The catheter is anchored as securely as possible to prevent it from moving in the urethra. Encrustations arising from urinary salts may serve as a nucleus for stone formation; however, using silicone catheters results in significantly less crust formation.

A liberal fluid intake, within the limits of the patient’s cardiac and renal reserve, and an increased urine output must be ensured to flush the catheter and to dilute urinary substances that might form encrustations.

Urine cultures are obtained as prescribed or indicated in monitoring the patient for infection; many catheters have an aspiration (puncture) port from which a specimen can be obtained.

Controversy exists about the usefulness of taking cultures and treating bacteriuria in patients who have symptoms of infection and who have indwelling catheters. Bacteriuria is considered to be inevitable, and overtreatment may lead to resistant strains of bacteria (Suchinski et al., 1999).

**MINIMIZING TRAUMA**

Trauma to the urethra can be minimized by:

- Using an appropriate-sized catheter
- Lubricating the catheter adequately with a water-soluble lubricant during insertion
- Inserting the catheter far enough into the bladder to prevent trauma to the urethral tissues when the retention balloon of the catheter is inflated

Manipulation of the catheter is the most common cause of trauma to the bladder mucosa in the catheterized patient. Infection then inevitably occurs when urine invades the damaged mucosa.

The catheter is secured properly to prevent it from moving, causing traction on the urethra, or being unintentionally removed, and care is taken to ensure that the catheter position permits leg movement. In male patients, the drainage tube (not the catheter) is taped laterally to the thigh to prevent pressure on the urethra at the penoscrotal junction, which can eventually lead to formation of a urethrocutaneous fistula. In female patients, the drainage tubing attached to the catheter is taped to the thigh to prevent tension and traction on the bladder.

Care is taken to ensure that any patient who is confused does not remove the catheter with the retention balloon still inflated. This could cause bleeding and considerable injury to the urethra (Phillips, 2000).

**RETRAINING THE BLADDER**

When an indwelling urinary catheter is in place, the detrusor muscle does not actively contract the bladder wall to stimulate emptying, because urine is continuously draining from the bladder. As a result, the detrusor may not immediately respond to bladder filling when the catheter is removed, resulting in either urine retention or urinary incontinence. This condition, known as postcatheterization detrusor instability, can be managed with bladder retraining (Chart 44-6).

Immediately after the indwelling catheter is removed, the patient is placed on a timed voiding schedule, usually every 2 to 3 hours. At the given time interval, the patient is instructed to void. The bladder is then scanned using a portable ultrasonic bladder scanner. If 100 mL or more of urine remains in the bladder, straight catheterization may be performed for complete bladder
**Physiology/Pathophysiology**

**CAUSES**
- Catheterization
  - Bacterial ascension
  - Bacterial colonization
  - Permanent bacteriuria
  - Manipulations of catheter
    - Change of catheter
    - Irrigation
    - Unintentional removal
  - Damaged mucosa

**PATHOPHYSIOLOGY**
- Bladder infection
  - Damaged and inflamed mucosa
    - Detrusor irritation
    - Detrusor spasms
      - Inflammatory cells
      - Red blood cells
      - Fibrin
      - Other glutinous products

**MANIFESTATIONS**
- Leakage
- CLINICAL SIGNS
  - Encrustation
  - Distention
  - Obstruction
  - Leakage
- URINALYSIS
  - Leukocytes
  - Urothelial cells
  - Erythrocytes

kidneys, reduces the incidence of urinary tract infections, and "im-

GuaranteedAssisting With Intermittent Self-Catheterization

Intermittent self-catheterization provides periodic drainage of urine from the bladder. By promoting drainage and eliminating excessive residual urine, intermittent catheterization protects the kidneys, reduces the incidence of urinary tract infections, and im-

Guidelines for Preventing Infection in the Catheterized Patient

- Use scrupulous aseptic technique during insertion of the catheter. Use a preassembled, sterile, closed urinary drainage system.
- To prevent contamination of the closed system, never disconnect the tubing. The drainage bag must never touch the floor. The bag and collecting tubing are changed if contamination occurs, if urine flow becomes obstructed, or if tubing junctions start to leak at the connections.
- If the collection bag must be raised above the level of the patient’s bladder, clamp the drainage tube. This prevents backflow of contaminated urine into the patient’s bladder from the bag.
- Ensure a free flow of urine to prevent infection. Improper drainage occurs when the tubing is kinked or twisted, allowing pools of urine to collect in the tubing loops.
- To reduce the risk of bacterial proliferation, empty the collection bag at least every 8 hours through the drainage spout—more frequently if there is a large volume of urine.
- Avoid contamination of the drainage spout. A receptacle in which to empty the bag is provided for each patient.
- Never irrigate the catheter routinely. If the patient is prone to obstruction from clots or large amounts of sediment, use a three-way system with continuous irrigation.
- Never disconnect the tubing to obtain urine samples, to irrigate the catheter, or to ambulate or transport the patient.
- Never leave the catheter in place longer than is necessary.
- Avoid routine catheter changes. The catheter is changed only to correct problems such as leakage, blockage, or encrustations.
- Avoid unnecessary handling or manipulation of the catheter by the patient or staff.
- Carry out hand hygiene before and after handling the catheter, tubing, or drainage bag.
- Wash the perineal area with soap and water at least twice a day; avoid a to-and-fro motion of the catheter. Dry the area well, but avoid applying powder because it may irritate the perineum.
- Monitor the patient’s voiding when the catheter is removed. The patient must void within 8 hours; if unable to void, the patient may require catheterization with a straight catheter.
- Obtain a urine specimen for culture at the first sign of infection.

emptying. After a few days, as the nerve endings in the bladder wall become aware of bladder filling and emptying, bladder function usually returns to normal. If the individual has had an indwelling catheter in place for an extended period, bladder retraining will take much longer; in some cases, function may never return to normal. If this occurs, long-term intermittent catheterization may become necessary (Phillips, 2000).

Chart 44-6 • PATIENT EDUCATION

Bladder Retraining After Indwelling Catheterization

- Instruct the patient to drink a measured amount of fluid from 8 AM to 10 PM to avoid bladder overdistention. Offer no fluids (except sips) after 10 PM.
- At specified times, ask the patient to void by applying pressure over the bladder, tapping the abdomen, or stretching the anal sphincter with a finger to trigger the bladder.
- Immediately after the voiding attempt, catheterize the patient to determine the amount of residual urine.
- Measure the volumes of urine voided and obtained by catheterization.
- Palpate the bladder at repeated intervals to assess for distention.
- Instruct the patient without usual sensation to be alert for any signs that indicate a full bladder, such as perspiration, cold hands or feet, and feelings of anxiety.
- Lengthen the intervals between catheterizations as the volume of residual urine decreases. Catheterization is usually discontinued when the volume of residual urine is at an acceptable level.

Assisting With Intermittent Self-Catheterization

Intermittent self-catheterization provides periodic drainage of urine from the bladder. By promoting drainage and eliminating excessive residual urine, intermittent catheterization protects the kidneys, reduces the incidence of urinary tract infections, and im-

- To reduce the risk of bacterial proliferation, empty the collection bag at least every 8 hours through the drainage spout—more frequently if there is a large volume of urine.
- Avoid contamination of the drainage spout. A receptacle in which to empty the bag is provided for each patient.
- Never irrigate the catheter routinely. If the patient is prone to obstruction from clots or large amounts of sediment, use a three-way system with continuous irrigation.
- Never disconnect the tubing to obtain urine samples, to irrigate the catheter, or to ambulate or transport the patient.
- Never leave the catheter in place longer than is necessary.
- Avoid routine catheter changes. The catheter is changed only to correct problems such as leakage, blockage, or encrustations.
- Avoid unnecessary handling or manipulation of the catheter by the patient or staff.
- Carry out hand hygiene before and after handling the catheter, tubing, or drainage bag.
- Wash the perineal area with soap and water at least twice a day; avoid a to-and-fro motion of the catheter. Dry the area well, but avoid applying powder because it may irritate the perineum.
- Monitor the patient’s voiding when the catheter is removed. The patient must void within 8 hours; if unable to void, the patient may require catheterization with a straight catheter.
- Obtain a urine specimen for culture at the first sign of infection.

improves continence. It is the treatment of choice in patients with spinal cord injury and other neurologic disorders, such as multiple sclerosis, when the ability to empty the bladder is impaired. Self-catheterization promotes independence, results in few complications, and enhances self-esteem and quality of life.

When teaching the patient how to perform self-catheterization, the nurse must use aseptic technique to minimize the risk of cross-contamination. The patient, however, may use a “clean” (non-sterile) technique at home, where the risk of cross-contamination is reduced. Either antibacterial liquid soap or povidone-iodine (Betadine) solution is recommended for cleaning urinary catheters at home. The catheter is thoroughly rinsed with tap water after soaking in the cleaning solution. It must dry before reuse. It should be kept in its own container, such as a plastic food-storage bag.

In teaching the patient, the nurse emphasizes the importance of frequent catheterization and emptying the bladder at the prescribed time. The average daytime clean intermittent catheterization schedule is every 4 to 6 hours and just before bedtime. If the patient is awakened at night with an urge to void, catheterization may be performed after an attempt to void (Reilly, 2001).

The female patient assumes a Fowler’s position and uses a mirror to help locate the urinary meatus. She inserts the catheter 7.5 cm (3 in) into the urethra, in a downward and backward direction. The male patient assumes a Fowler’s or sitting position, lubricates the catheter and retracts the foreskin of the penis with one hand while grasping the penis and holding it at a right angle to the body. (This maneuver straightens the urethra and makes it easier to insert the catheter.) He inserts the catheter 15 to 25 cm (6 to 10 in) until urine begins to flow. After removal, the catheter is cleaned, rinsed, and wrapped in a paper towel or placed in a plastic bag or case. Patients following this routine should consult a primary health care provider at regular intervals to assess urinary function and to detect complications.

If the patient cannot perform intermittent self-catheterization, a family member may be taught to carry out the procedure at regular intervals during the day.

Another self-catheterization option is creation of the Mitrofanoff umbilical appendicovesicostomy, which provides easy ac-
cess to the bladder. In this procedure, the bladder neck is closed and the appendix is used to gain access to the bladder from the skin surface. A submucosal tunnel is created with the appendix; one end of the appendix is brought to the skin surface and used as a stoma and the other end is tunneled into the bladder. The appendix may be used as an artificial urinary sphincter when an alternative is necessary to empty the bladder. In children, the most common reason for the procedure is spina bifida. In adults, a surgically prepared continent urine reservoir with a sphincter mechanism is required in cases of bladder cancer, severe interstitial cystitis, or in males, bladder extrophy-epispadias complex when a radical cystectomy (surgical removal of the bladder) is necessary. This procedure for surgically creating a sphincter, which is attached to an internal pouch reservoir that can be catheterized, is possible only in individuals who have a healthy appendix (Kajbafzadeh & Chubak, 2001; Uygur et al., 2001).

**Dialysis**

Dialysis is used to remove fluid and uremic waste products from the body when the kidneys cannot do so. It may also be used to treat patients with edema that does not respond to treatment, hepatic coma, hyperkalemia, hypercalcemia, hypertension, and uremia. Methods of therapy include hemodialysis, continuous renal replacement therapy (CRRT; discussed later), and various forms of peritoneal dialysis. The need for dialysis may be acute or chronic.

Acute dialysis is indicated when there is a high and rising level of serum potassium, fluid overload, or impending pulmonary edema, increasing acidosis, pericarditis, and severe confusion. It may also be used to remove certain medications or other toxins (poisoning or medication overdose) from the blood.

Chronic or maintenance dialysis is indicated in chronic renal failure, known as end-stage renal disease (ESRD), in the following instances: the presence of uremic signs and symptoms affecting all body systems (nausea and vomiting, severe anorexia, increasing lethargy, mental confusion), hyperkalemia, fluid overload not responsive to diuretics and fluid restriction, and a general lack of well-being. An urgent indication for dialysis in patients with chronic renal failure is pericardial friction rub.

Patients with no renal function can be maintained by dialysis for years. Although the costs of dialysis are usually reimbursable, limitations on the patient’s ability to work resulting from illness and dialysis usually impose a great financial burden on patients and families.

The decision to initiate dialysis should be reached only after thoughtful discussion among the patient, family, physician, and others as appropriate. Many potentially life-threatening issues are associated with the need for dialysis. The nurse can assist the patient and family by answering their questions, clarifying the information provided, and supporting their decision. The lifestyle changes that patients needing hemodialysis eventually need to make are often overwhelming. Sometimes the news that a donor kidney is available for transplantation can be so disruptive to the changes in lifestyle that were made to accommodate hemodialysis that the patient may stall the process required for transplantation or refuse the kidney when it becomes available, choosing instead to continue with hemodialysis.

No “gold standard” is available to assess the compliance of hemodialysis patients (Kaveh & Kimmel, 2001), and methods to do so vary from one dialysis facility to the next. Therefore, it is difficult to assess how many deaths are due to natural causes and how many are due to patients’ noncompliance with treatment.

Successful kidney transplantation eliminates the need for dialysis. Not only is the quality of life much improved in patients with ESRD who undergo transplantation, but physiologic function, such as heart rate variability, is improved as well (Hathaway, Wicks, Cashion, et al., 2000). Patients who undergo renal transplantation from living donors before dialysis is initiated generally have longer survival of the transplanted kidney than patients who receive transplantation after dialysis treatment is initiated (Mange, Joffe & Feldman, 2001).

**HEMODIALYSIS**

Hemodialysis is the most commonly used method of dialysis: more than 300,000 Americans currently receive hemodialysis (Parker, Bliwise & Rye, 2000). It is used for patients who are acutely ill and require short-term dialysis (days to weeks) and for patients with ESRD who require long-term or permanent therapy. A dialyzer (once referred to as an artificial kidney) serves as a synthetic semipermeable membrane, replacing the renal glomeruli and tubules as the filter for the impaired kidneys.

For patients with chronic renal failure, hemodialysis prevents death, although it does not cure renal disease and does not compensate for the loss of endocrine or metabolic activities of the kidneys. Patients receiving hemodialysis must undergo treatment for the rest of their lives or until they undergo a successful kidney transplant. Treatments usually occur three times a week for at least 3 to 4 hours per treatment (some patients undergo short-daily hemodialysis; Chart 44-7). Patients receive chronic or maintenance dialysis when they require dialysis therapy for survival and control of uremic symptoms. The trend in managing ESRD is to initiate treatment before the signs and symptoms associated with uremia become severe.

**Principles of Hemodialysis**

The objectives of hemodialysis are to extract toxic nitrogenous substances from the blood and to remove excess water. In hemodialysis, the blood, laden with toxins and nitrogenous wastes, is diverted from the patient to a machine, a dialyzer, in which the blood is cleansed and then returned to the patient.

**Diffusion, osmosis, and ultrafiltration** are the principles on which hemodialysis is based. The toxins and wastes in the blood are removed by diffusion—that is, they move from an area of higher concentration in the blood to an area of lower concentration in the dialysate. The dialysate is a solution made up of all the important electrolytes in their ideal extracellular concentrations. The electrolyte level in the patient’s blood can be brought under control by properly adjusting the dialysate bath. The semipermeable membrane impedes the diffusion of large molecules, such as red blood cells and proteins.

Excess water is removed from the blood by osmosis, in which water moves from an area of higher solute concentration (the blood) to an area of lower solute concentration (the dialysate bath). Ultrafiltration is defined as water moving under high pressure to an area of lower pressure. This process is much more efficient at water removal than osmosis. Ultrafiltration is accomplished by applying negative pressure or a suctioning force to the dialysis membrane. Because patients with renal disease usually cannot excrete water, this force is necessary to remove fluid to achieve fluid balance.
The body’s buffer system is maintained using a dialysate bath made up of bicarbonate (most common) or acetate, which is metabolized to form bicarbonate. The anticoagulant heparin is administered to keep blood from clotting in the dialysis circuit. Cleansed blood is returned to the body. By the end of the dialysis treatment, many waste products have been removed, the electrolyte balance has been restored to normal, and the buffer system has been replenished.

**Equipment: Dialyzers**

Most dialyzers, or artificial kidneys, are either flat-plate dialyzers or hollow-fiber artificial kidneys that contain thousands of tiny cellophane tubules that act as semipermeable membranes. The blood flows through the tubules, while a solution (the dialysate) circulates around the tubules. The exchange of wastes from the blood to the dialysate occurs through the semipermeable membrane of the tubules (Fig. 44-4).

Dialyzers have undergone many technological changes. The difference between flat-plate dialyzers and hollow-fiber dialyzers lies in performance and biocompatibility. Biocompatibility refers to the ability of the dialyzer to accomplish its objectives without causing hypersensitive, allergic, or adverse reactions. Some dialyzers remove middle-weight molecules at a faster rate and ultrafiltrate at higher rates, which is thought to reduce neuropathy of the lower extremities, a complication of long-term hemodialysis.

In general, the more efficient the dialyzer, the higher the cost.

Another technological advance is high-flux dialysis, which uses highly permeable membranes that increase the clearance of low- and mid-molecular-weight molecules. These special membranes are used with higher-than-traditional rates of flow for the blood entering and exiting the dialyzer (500 to 800 mL/min). High-flux dialysis requires the use of precise volumetric ultrafiltration control systems, and not every dialysis unit can perform this type of dialysis. High-flux dialysis increases the efficiency of treatments while shortening their duration and reducing the need for heparin.

**Chart 44-7**

*Short, Daily Hemodialysis*

With an increasing number of individuals receiving hemodialysis, cost issues continue to be of concern to both insurance companies and patients. Some think that daily hemodialysis may improve clinical outcomes and reduce hospital days, thereby justifying the cost of daily dialysis. Daily dialysis can be safely delivered in the clinical setting by health professionals or in the home setting by patients and family members trained in the procedure. Although short, daily hemodialysis was originally described in 1969, it lost favor when large clinical dialysis centers emerged in the 1970s.

Daily hemodialysis can be completed by the short, high-efficiency method or the slow, nocturnal method. To date, there are no studies demonstrating that one method is superior to the other. Patients in both groups have a higher success rate than those receiving three traditional hemodialysis treatments per week, and quality of life is significantly increased as well. Anemia is reduced, thus decreasing the need for EpoGen. Blood pressure and volume management is better with daily dialysis. Although the economic impact of daily dialysis is yet unknown, the general premise appears to be that the higher dialysis costs will be offset by lower morbidity rates, including fewer acute hospitalizations and lower overall medication costs (Fagugli et al., 2001; Lindsay & Kortas, 2001; Mohr et al., 2001).

**Figure 44-4**

Hemodialysis system. (A) Blood from an artery is pumped into (B) a dialyzer where it flows through the cellophane tubes, which act as the semipermeable membrane (*inset*). The dialysate, which has the same chemical composition as the blood except for urea and waste products, flows in around the tubes. The waste products in the blood diffuse through the semipermeable membrane into the dialysate.
Because of the costs associated with hemodialysis, hemodialyzers are commonly reused in dialysis centers in the United States. Recent studies have raised concerns about the mortality risks associated with some hemodialyzer reuse practices. Results from the United States Renal Data System (USRDS) Dialysis Morbidity and Mortality Study demonstrated differences in mortality rate with the reuse of certain hemodialyzers. Among all membranes, mortality is lowest for patients treated with high-flux synthetic membranes. The bleaching process to reuse high-flux synthetic membrane dialyzers may account for the lower mortality rate; with this process, clearance of larger molecules is still possible, even though the hemodialyzer is not new. These findings are important because high-flux hemodialyzers are very efficient and are used in most dialysis centers (Port, Wolfe, Hulbert-Shearson et al., 2001).

**Vascular Access**

Access to the patient’s vascular system must be established to allow blood to be removed, cleansed, and returned to the patient’s vascular system at rates between 200 and 800 mL/minute. Several types of access are available.

**SUBCLAVIAN, INTERNAL, JUGULAR, AND FEMORAL CATHETERS**

Immediate access to the patient’s circulation for acute hemodialysis is achieved by inserting a double-lumen or multilumen catheter into the subclavian, internal jugular, or femoral vein. Although this method of vascular access involves some risk (eg, hematoma, pneumothorax, infection, thrombosis of the subclavian vein, and inadequate flow), it can be used for several weeks. The catheters are removed when no longer needed, because the patient’s condition has improved or another type of access has been established. Double-lumen, cuffed catheters may also be surgically inserted into the subclavian vein of patients requiring a central venous catheter for dialysis (Fig. 44-5).

**FISTULA**

A more permanent access, known as a fistula, is created surgically (usually in the forearm) by joining (anastomosing) an artery to a vein, either side to side or end to end (Fig. 44-6). Needles are inserted into the vessel to obtain blood flow adequate to pass through the dialyzer. The arterial segment of the fistula is used for arterial flow and the venous segment for reinfusion of the dialyzed blood. The fistula takes 4 to 6 weeks to mature before it is ready for use. This gives time for healing and for the venous segment of the fistula to dilate to accommodate two large-bore (14- or 16-gauge) needles. The patient is encouraged to perform exercises to increase the size of these vessels (ie, squeezing a rubber ball for forearm fistulas) and thereby to accommodate the large-bore needles used in hemodialysis.

**GRAFT**

An arteriovenous graft can be created by subcutaneously interposing a biologic, semibiologic, or synthetic graft material between an artery and vein (see Fig. 44-6). The most commonly used synthetic graft material is expanded polytetrafluoroethylene (PTFE). Usually, a graft is created when the patient’s vessels are not suitable for a fistula. Patients with compromised vascular systems (eg, from diabetes) often need to have a graft to undergo hemodialysis. Grafts are usually placed in the forearm, upper arm, or upper thigh. Infection and thrombosis are the most common complications of arteriovenous grafts.

**Complications of Hemodialysis**

Although hemodialysis can prolong life indefinitely, it does not alter the natural course of the underlying kidney disease, nor does it completely replace kidney function. The patient is subject to a number of problems and complications. One leading cause of death among patients undergoing maintenance hemodialysis is atherosclerotic cardiovascular disease. Disturbances of lipid metabolism (hypertriglyceridemia) appear to be accentuated by hemodialysis. Heart failure, coronary heart disease and anginal pain, stroke, and peripheral vascular insufficiency may occur and may incapacitate the patient. Anemia and fatigue contribute to diminished physical and emotional well-being, lack of energy and drive, and loss of interest, although the use of erythropoietin (EpoGEN) before the start of dialysis has been shown to have a significant effect on hematocrit values for the first 19 months after starting dialysis (Fink et al., 2001). Increased dialyzer clotting may occur, which is prevented by adjusting heparin doses, and dialyzer solute clearances may decrease slightly (Eschbach & Adamson, 1989).

Gastric ulcers and other gastrointestinal problems occur from the physiologic stress of chronic illness, medication, and related problems. Disturbed calcium metabolism leads to renal osteodystrophy that produces bone pain and fractures. Other problems
include fluid overload associated with heart failure, malnutrition, infection, neuropathy, and pruritus.

Up to 85% of people undergoing hemodialysis experience major sleep problems that further complicate their overall health status. Recent studies suggest that early-morning or late-afternoon dialysis may be a risk factor for developing sleep abnormalities. Researchers suggest such interventions as changing the temperature of the dialysate bath to prevent temperature elevation and limiting napping during dialysis as strategies to reduce sleep problems in individuals receiving hemodialysis (Parker et al., 2000). Other complications of dialysis treatment may include the following:

- Hypotension may occur during the treatment as fluid is removed. Nausea and vomiting, diaphoresis, tachycardia, and dizziness are common signs of hypotension.
- Painful muscle cramping may occur, usually late in dialysis as fluid and electrolytes rapidly leave the extracellular space.
- Exsanguination may occur if blood lines separate or dialysis needles accidentally become dislodged.
- Dysrhythmias may result from electrolyte and pH changes or from removal of antiarrhythmic medications during dialysis.
- Air embolism is rare but can occur if air enters the vascular system.
- Chest pain may occur in patients with anemia or arteriosclerotic heart disease.
- Dialysis disequilibrium results from cerebral fluid shifts. Signs and symptoms include headache, nausea and vomiting, restlessness, decreased level of consciousness, and seizures. It is more likely to occur in acute renal failure or when blood urea nitrogen levels are very high (exceeding 150 mg/dL).

Long-Term Management

During dialysis, the patient, the dialyzer, and the dialysate bath require constant monitoring because numerous complications are possible, including air embolism, inadequate or excessive ultrafiltration (hypotension, cramping, vomiting), blood leaks, contamination, and access complications. The nurse in the dialysis unit has an important role in monitoring, supporting, assessing, and educating the patient. Nursing care of the patient and maintenance of the access device are discussed under “Care of the Hospitalized Dialysis Patient.”

Pharmacologic Therapy

Just as many medications are excreted wholly or in part by the kidneys, many medications are removed from the blood during hemodialysis; therefore, the physician may need to adjust the dosage. Metabolites of drugs that are bound to protein are not removed during dialysis. Removal of other drug metabolites depends on the weight and size of the molecule.

Patients undergoing hemodialysis who require medications (eg, cardiac glycosides, antibiotic agents, antiarrhythmic medications, antihypertensive agents) are monitored closely to ensure that blood and tissue levels of these medications are maintained without toxic accumulation.

In patients receiving dialysis, all medications and their dosages must be carefully evaluated. Antihypertensive therapy, often part of the dialysis patient’s regimen, is one example in which communication, teaching, and evaluation can make a difference in patient outcomes. The patient must know when and when not to take the medication. For example, if an antihypertensive agent is taken on a dialysis day, a hypotensive effect may occur during dialysis, causing dangerously low blood pressure. Many medications that are taken once daily can be held until after the dialysis treatment.

Nutritional and Fluid Therapy

When damaged kidneys cannot excrete end products of metabolism, these substances accumulate in the serum as toxins. The resulting symptoms, collectively known as uremic symptoms or uremic syndrome, affect every body system. The more toxins that accumulate, the more severe the symptoms.

Diet is an important factor for patients on hemodialysis because of the effects of uremia. Goals of nutritional therapy are to minimize uremic symptoms and fluid and electrolyte imbalances; to maintain good nutritional status through adequate protein, calorie, vitamin, and mineral intake; and to enable the patient to eat a palatable and enjoyable diet. Restricting dietary protein decreases the accumulation of nitrogenous wastes, reduces uremic symptoms, and may even postpone the initiation of dialysis for a few months. Restriction of fluid is also part of the dietary prescription because fluid accumulation may occur, leading to weight gain, heart failure, and pulmonary edema.

With the initiation of hemodialysis, the patient’s dietary intake usually still requires some restriction of dietary protein, sodium, potassium, and fluid intake. Protein intake is restricted to about 1 g/kg ideal body weight per day; therefore, protein must be of high biologic quality and consist of the essential amino acids to prevent poor protein use and to maintain a positive nitrogen balance. Examples of foods high in biologic protein content include eggs, meat, milk, poultry, and fish. Sodium is usually restricted to 2 to 3 g/day; fluids are restricted to an amount equal to the daily urine output plus 500 mL/day. The goal for hemodialysis patients is to keep their interdialytic (between dialysis treatments) weight gain under 1.5 kg. Potassium restriction (average 1.5 to 2.5 g/day) depends on the amount of residual renal function and the frequency of dialysis (National Kidney Foundation, 2000).
Dietary restriction is an unwelcome change in lifestyle for many patients with chronic renal failure. Patients often feel stigmatized in social situations because there may be few food selections available for their diet. If the restrictions are ignored, life-threatening complications, such as hyperkalemia and pulmonary edema, may result. Thus, the patient may feel punished for responding to basic human drives to eat and drink. The nurse who encounters a patient with symptoms or complications resulting from dietary indiscretion must avoid harsh, judgmental, or punitive tones when communicating with him or her.

Nursing Management

Patients requiring long-term hemodialysis are often concerned about the unpredictability of the illness and the disruption of their lives. They often have financial problems, difficulty holding a job, waning sexual desire and impotence, depression from being chronically ill, and fear of dying. Younger patients worry about marriage, having children, and the burden that they bring to their families. The regimented lifestyle that frequent dialysis treatments and restrictions in food and fluid intake impose is often demoralizing to the patient and family.

MEETING PSYCHOSOCIAL NEEDS

Dialysis alters the lifestyle of the patient and family. The amount of time required for dialysis and physician visits and being chronically ill can create conflict, frustration, guilt, and depression. It may be difficult for the patient, spouse, and family to express anger and negative feelings.

The nurse needs to give the patient and family the opportunity to express feelings of anger and concern over the limitations that the disease and treatment impose and over possible financial problems and job insecurity. If anger is not expressed, it may be directed inward and lead to depression, despair, and attempts at suicide (suicide is more prevalent in dialysis patients); however, if anger is projected outward to other people, it may destroy already threatened family relationships.

Although normal in this situation, these feelings are often profound and overwhelming. Counseling and psychotherapy may be necessary. Depression may require treatment with antidepressant agents. Referring the patient and family to a mental health provider with expertise in the care of patients receiving dialysis may also be helpful. Clinical nurse specialists, psychologists, and social workers may be helpful in assisting the patient and family to cope with the changes brought about by renal failure and its treatment.

The sense of loss that the patient experiences cannot be underestimated because every aspect of a “normal life” is disrupted. Some patients use denial to deal with the overwhelming array of medical problems (eg, infections, hypertension, anemia, neuropathy). Staff who are tempted to label the patient as noncompliant must consider the impact of renal failure and its treatment on the patient and family and the coping strategies that they may use. The nurse helps the patient to identify safe, effective coping strategies to cope with these ever-present problems and fears (Tonelli et al., 2001).

PROMOTING HOME AND COMMUNITY-BASED CARE

Preparing a patient for hemodialysis is challenging. Often the patient does not fully comprehend the impact of dialysis, and learning needs may go unrecognized. Good communication between the dialysis staff (in the hospital and outpatient clinic), unit staff, and home care nurses is essential for providing sound, continuous care.

Teaching Patients Self-Care. Assessment helps identify the learning needs of the patient and family members. In many cases, the patient is home before learning needs and readiness to learn can be thoroughly evaluated; therefore, hospital-based nurses, dialysis staff, and home care nurses must work together to provide appropriate teaching that meets the patient’s and family’s changing needs and readiness to learn.

The diagnosis of chronic renal failure and the need for dialysis often overwhelm the patient and family. In addition, many patients with ESRD have depressed mentation, a shortened attention span, a decreased level of concentration, and altered perceptual states. Therefore, teaching must occur in brief, 10- to 15-minute sessions, with time added for clarification, repetition, reinforcement, and questions from the patient and family. The nurse needs to convey a nonjudgmental attitude to enable the patient and family to discuss options and their feelings about those options. Team conferences are helpful for sharing information and providing every team member the opportunity to discuss the needs of the patient and family.

Teaching Patients About Hemodialysis. Although most patients who require hemodialysis undergo the procedure in an outpatient setting, home hemodialysis is an option for some. Home hemodialysis requires a highly motivated patient who is willing to take responsibility for the procedure and is able to adjust each treatment to meet the body’s changing needs. It also requires the commitment and cooperation of a family member to assist the patient. Many patients, however, are not comfortable imposing on others in that way and do not wish to subject family members to the feeling that their home is being turned into a clinic.

The health care team should never force a patient into using home hemodialysis. Because this treatment requires many significant changes in the home and family, home hemodialysis must be the patient’s and family’s decision.

The patient undergoing home hemodialysis and the caregiver assisting that patient must be trained to prepare, operate, and disassemble the dialysis machine; maintain and clean the equipment; administer medications (eg, heparin) into the machine lines; and handle emergency problems (hemodialysis dialyzer rupture, electrical or mechanical problems, hypotension, shock, and seizures). Because home hemodialysis places primary responsibility for the treatment on the patient and the family member, they must understand and be capable of performing all aspects of the hemodialysis procedure (Chart 44-8).

Before home hemodialysis is initiated, the home environment, household and community resources, and ability and willingness of the patient and family to carry out this treatment are assessed. The home is surveyed to see if electrical outlets, plumbing facilities, and storage space are adequate. Modifications may be needed to enable the patient and assistant to perform dialysis safely and to deal with emergencies.

Once home dialysis is initiated, the home care nurse must visit periodically to evaluate compliance with the recommended techniques, to assess the patient for complications, to reinforce previous teaching, and to provide reassurance.

Continuing Care. The health care team’s goal in treating patients with chronic renal failure is to maximize their vocational potential, functional status, and quality of life. To facilitate renal rehabilitation, appropriate follow-up and monitoring by members of the health care team (physicians, dialysis nurses, social workers, psychologist, home care nurses, and others as appropriate) are

Several types of continuous renal replacement therapy (CRRT) are available and are widely used in critical care units. CRRT may be indicated for patients who have acute or chronic renal failure and who are too clinically unstable for traditional hemodialysis, for patients with fluid overload secondary to oliguric (low urine output) renal failure, and for patients whose kidneys cannot handle their acutely high metabolic or nutritional needs. CRRT does not produce rapid fluid shifts, does not require dialysis machines or dialysis personnel to carry out the procedures, and can be initiated quickly in hospitals without dialysis facilities.

CRRT methods are similar to hemodialysis methods in that they require access to the circulation and blood to pass through an artificial filter. A hemofilter (an extremely porous blood filter containing a semipermeable membrane) is used in all CRRT methods, which are described below (Astle, 2001).

Continuous Arteriovenous Hemofiltration

Continuous arteriovenous hemofiltration (CAVH) was first used in 1977 to treat fluid overload. Blood is circulated through a small-volume, low-resistance filter, using the patient’s arterial pressure rather than that of the blood pump as is used in hemodialysis. Blood flows from an artery (usually by an arterial catheter in the femoral artery) to a hemofilter. A pressure gradient is necessary for optimal filtration; cannulation of the femoral artery and vein provides the necessary gradient (difference) in arterial and venous pressures. The filtered blood then returns to the patient’s circulation through a venous catheter. Intravenous fluids may be administered to replace fluid removed by the procedure. With CAVH, there is no concentration gradient, so only fluid is filtered. Electrolytes are eliminated only as they are pulled along and removed with the fluid. Ultrafiltrate is collected in a drainage bag, measured, and discarded. CAVH is usually set up and initiated by trained dialysis staff and then maintained and monitored by critical care personnel.
Continuous Arteriovenous Hemodialysis

Continuous arteriovenous hemodialysis (CAVHD) has many of the characteristics of CAVH but offers the advantage of a concentration gradient for faster clearance of urea. This is accomplished by the circulation of dialysate on one side of a semi-permeable membrane. The blood flow through the system depends on the patient’s arterial pressure, as in CAVH; a blood pump is not used as it is in standard hemodialysis. CAVHD is usually set up and initiated by trained dialysis staff and then maintained and monitored by critical care personnel.

Continuous Venovenous Hemofiltration

Continuous venovenous hemofiltration (CVVH) is increasingly being used in managing acute renal failure. Blood from a double-lumen venous catheter is pumped (using a small blood pump) through a hemofilter and then returned to the patient through the same catheter (Fig. 44-7). CVVH provides continuous slow fluid removal (ultrafiltration); therefore, hemodynamic effects are mild and better tolerated by patients with unstable conditions. CVVH has several other benefits over CAVH in that no arterial access is required and critical care nurses can set up, initiate, maintain, and terminate the system.

Continuous Venovenous Hemodialysis

Continuous venovenous hemodialysis (CVVHD) is similar to CVVH. Blood is pumped from a double-lumen venous catheter through a hemofilter and returned to the patient through the same catheter. In addition to the benefits of ultrafiltration, CVVHD uses a concentration gradient to facilitate the removal of uremic toxins. Therefore, no arterial access is required, hemodynamic effects are usually mild, and critical care nurses can set up, initiate, maintain, and terminate the system.

Peritoneal Dialysis

The goals of peritoneal dialysis are to remove toxic substances and metabolic wastes and to re-establish normal fluid and electrolyte balance. Peritoneal dialysis may be the treatment of choice for patients with renal failure who are unable or unwilling to undergo hemodialysis or renal transplantation. Patients who are susceptible to the rapid fluid, electrolyte, and metabolic changes that occur during hemodialysis experience fewer of these problems with the slower rate of peritoneal dialysis. Therefore, patients with diabetes or cardiovascular disease, many older patients, and those who may be at risk for adverse effects of systemic heparin are likely candidates for peritoneal dialysis. Additionally, severe
time depends on the type of peritoneal dialysis. Peritoneal dialysis can be performed using several different approaches: acute, intermittent peritoneal dialysis; continuous ambulatory peritoneal dialysis (CAPD); and continuous cyclic peritoneal dialysis (CCPD). These three methods are discussed later in this chapter. As with other forms of treatment, the decision to begin peritoneal dialysis is made by the patient and family in consultation with the physician.

Although specific patient populations do benefit from peritoneal dialysis, it is not as efficient as hemodialysis (Lindsay & Kortas, 2001). Because cardiovascular disease is the cause of death in half of all patients with ESRD, the adequacy of dialysis must be defined, in part, by its potential to reduce cardiovascular disease. Blood pressure, volume, left ventricular hypertrophy, and dyslipidemias are the major causes of morbidity and mortality in patients undergoing peritoneal dialysis (Charoth, Golper & Gokal, 1999).

**Underlying Principles**

In peritoneal dialysis, the peritoneum, a serous membrane that covers the abdominal organs and lines the abdominal wall, serves as the semipermeable membrane. The surface of the peritoneum constitutes a body surface area of about 22,000 cm². Sterile dialysate fluid is introduced into the peritoneal cavity through an abdominal catheter at intervals (Fig. 44-8). Urea and creatinine, metabolic end products normally excreted by the kidneys, are cleared from the blood by diffusion and osmosis as waste products.

**FIGURE 44-8** In peritoneal dialysis and in acute intermittent peritoneal dialysis, dialysate is infused into the peritoneal cavity by gravity, after which the clamp on the infusion line is closed. After a dwell time (when the dialysate is in the peritoneal cavity), the drainage tube is unclamped and the fluid drains from the peritoneal cavity, again by gravity. A new container of dialysate is infused as soon as drainage is complete. The duration of the dwell time depends on the type of peritoneal dialysis.

**Procedure**

The patient undergoing peritoneal dialysis may be acutely ill, thus requiring short-term treatment to correct severe disturbances in fluid and electrolyte status, or may have chronic renal failure and need to receive ongoing treatments.

**PREPARING THE PATIENT**

The nurse’s preparation of the patient and family for peritoneal dialysis depends on the patient’s physical and psychological status, level of alertness, previous experience with dialysis, and understanding of and familiarity with the procedure.

The nurse explains the procedure to the patient and obtains signed consent for it. Baseline vital signs, weight, and serum electrolyte levels are recorded. The patient is encouraged to empty the bladder and bowel to reduce the risk of puncturing internal organs. The nurse also assesses the patient’s anxiety about the procedure and provides support and instruction. Broad-spectrum antibiotic agents may be administered to prevent infection. If the peritoneal catheter is to be inserted in the operating room, this is explained to the patient and family.

**PREPARING THE EQUIPMENT**

In addition to assembling the equipment for peritoneal dialysis, the nurse consults with the physician to determine the concentration of dialysate to be used and the medications to be added to it. Heparin may be added to prevent blood clotting and resultant occlusion of the peritoneal catheter. Potassium chloride may be prescribed to prevent hypokalemia. Antibiotics may be added to treat peritonitis. Insulin may be added for diabetic patients; a larger-than-normal dose may be needed, however, because about 10% of the insulin binds to the dialysate container. All medications are added immediately before the solution is instilled. Aseptic technique is crucial.

Before medications are added, the dialysate is warmed to body temperature to prevent patient discomfort and abdominal pain and to dilate the vessels of the peritoneum to increase urea clearance. Solutions that are too cold cause pain and vasoconstriction and reduce clearance. Solutions that are too hot burn the peritoneum. Dry heating is recommended (heating cabinet, incubator, or heating pad). Microwave heating of the fluid is not recommended because of the danger of burning the peritoneum.

Immediately before initiating dialysis, the nurse assembles the administration set and tubing. The tubing is filled with the prepared dialysate to reduce the amount of air entering the catheter and peritoneal cavity, which could increase abdominal discomfort and interfere with instillation and drainage of the fluid.

**INSERTING THE CATHETER**

Ideally, the peritoneal catheter is inserted in the operating room to maintain surgical asepsis and minimize the risk of contamination. In some circumstances, however, the physician inserts the catheter at the bedside under strict asepsis.
A rigid stylet catheter is inserted for acute peritoneal dialysis use only. Before the procedure, the skin is prepared with a local antiseptic to reduce skin bacteria and the risk of contamination and infection. The physician anesthetizes the site with a local anesthetic agent before making a small incision or stab wound in the lower abdomen, 3 to 5 cm below the umbilicus. Because this area is relatively free from large blood vessels, little bleeding occurs. A trocar is used to puncture the peritoneum as the patient tightens the abdominal muscles by raising the head. The catheter is threaded through the trocar and positioned. Previously prepared dialysate is infused into the peritoneal cavity, pushing the omentum (peritoneal lining extending from the abdominal organs) away from the catheter. The physician may then secure the catheter with a purse-string suture and apply antibacterial ointment and a sterile dressing over the site.

Catheters for long-term use (Tenckhoff, Swan, Cruz) are usually made of silicone and are radiopaque to permit visualization on x-ray. These catheters have three sections: (1) an intraperitoneal section, with numerous openings and an open tip to let dialysate flow freely; (2) a subcutaneous section that passes from the peritoneal membrane and tunnels through muscle and subcutaneous fat to the skin; and (3) an external section for connection to the dialysate system. Most of these catheters have two cuffs, which are made of Dacron polyester. The cuffs stabilize the catheter, limit movement, prevent leaks, and provide a barrier against microorganisms. One cuff is placed just distal to the peritoneum, and the other cuff is placed subcutaneously. The subcutaneous tunnel (5 to 10 cm long) further protects against bacterial infection (Fig. 44-9).

**PERFORMING THE EXCHANGE**

Peritoneal dialysis involves a series of exchanges or cycles. An exchange is defined as the infusion, dwell, and drainage of the dialysate. This cycle is repeated throughout the course of the dialysis. The dialysate is infused by gravity into the peritoneal cavity. A period of about 5 to 10 minutes is usually required to infuse 2 L of fluid. The prescribed dwell, or equilibration, time allows diffusion and osmosis to occur. Diffusion of small molecules, such as urea and creatinine, peaks in the first 5 to 10 minutes of the dwell time. At the end of the dwell time, the drainage portion of the exchange begins. The tube is unclamped and the solution drains from the peritoneal cavity by gravity through a closed system. Drainage is usually completed in 10 to 30 minutes. The drainage fluid is normally colorless or straw-colored and should not be cloudy. Bloody drainage may be seen in the first few exchanges after insertion of a new catheter but should not occur after that time. The entire exchange (infusion, dwell time, and drainage) takes 1 to 4 hours, depending on the prescribed dwell time. The number of cycles or exchanges and their frequency are prescribed based on the patient’s physical status and acuity of illness.

The removal of excess water during peritoneal dialysis is achieved by using a hypertonic dialysate with a high dextrose concentration that creates an osmotic gradient. Dextrose solutions of 1.5%, 2.5%, and 4.25% are available in several volumes, from 500 mL to 3,000 mL, allowing the dialysate selection to fit the patient’s tolerance, size, and physiologic needs. The higher the dextrose concentration, the greater the osmotic gradient and the more water removed. Selection of the appropriate solution is based on the patient’s fluid status.
Complications of Peritoneal Dialysis

Peritoneal dialysis is not without complications. Most are minor, but several, if unattended, can have serious consequences.

**PERITONITIS**

Peritonitis (inflammation of the peritoneum) is the most common and most serious complication of peritoneal dialysis. The organism responsible for peritoneal dialysis-related peritonitis is an important factor in clinical outcome and the basis of treatment guidelines. There has been a significant decrease in the rate of cases of peritonitis, from 1.37 episodes/patient-year in 1991 to 0.55 episodes/patient-year in 1998. *Staphylococcus aureus* and *Staphylococcus epidermidis* remain the most common Gram-positive organisms responsible for peritonitis, although the rates of each have decreased. *Pseudomonas aeruginosa*, *E. coli*, and *Klebsiella* species are the most common causes of Gram-negative peritonitis. Resistance to antibacterial agents (ie, ciprofloxacin, methicillin) used in their treatment increased dramatically from 1991 to 1998 (Zelenitsky et al., 2000).

Peritonitis is characterized by cloudy dialysate drainage, diffuse abdominal pain, and rebound tenderness. Hypotension and other signs of shock may occur if *S. aureus* is the responsible organism. The patient with peritonitis may be treated as an inpatient or outpatient (most common), depending on the severity of the infection and the patient’s clinical status. Initially, one to three rapid exchanges with a 1.5% dextrose solution without added medications are completed to wash out mediators of inflammation and to reduce abdominal pain. Drainage fluid is examined for cell count, and Gram’s stain and culture are used to identify the organism and guide treatment. Antibiotic agents (aminoglycosides or cephalosporins) are usually added to subsequent exchanges until the Gram’s stain or culture results are available for appropriate antibiotic determination. Intraperitoneal administration of antibiotics is as effective as intravenous administration. Antibiotic therapy continues for 10 to 14 days. Careful calculation of the antibiotic dosage helps prevent nephrotoxicity and further compromise of renal function.

Heparin (500 to 1,000 U/L) may be added to the dialysate to prevent fibrin clot formation; oral administration of low-dose warfarin (Coumadin) is also effective in decreasing coagulation factors and preventing thrombosis without increasing the risk of bleeding (Kim, Lee, Park et al., 2001).

Peritonitis that is unresolved after 4 days of appropriate therapy necessitates catheter removal. The patient is maintained on hemodialysis for about 1 month before a new catheter is inserted. In patients with fungal peritonitis, the peritoneal catheter must be removed if there is no response to therapy in 4 to 7 days. Tunnel infections and fecal peritonitis also necessitate catheter removal. Systemic antibiotics should continue for 5 to 7 days after catheter removal.

Regardless of which organism causes peritonitis, the patient with peritonitis loses large amounts of protein through the peritoneum. Acute malnutrition and delayed healing may result. Therefore, attention must be given to detecting and promptly treating the infections.

**LEAKAGE**

Leakage of dialysate through the catheter site may occur immediately after the catheter is inserted. Usually, the leak stops spontaneously if dialysis is withheld for several days to give the incision and exit site time to heal. During this time, it is important to reduce factors that might delay healing, such as undue abdominal muscle activity and straining during bowel movement. Leakage through the exit site or into the abdominal wall can occur for months or years after catheter placement. In many cases, leakage can be avoided by using small volumes (100 to 200 mL) of dialysate, gradually increasing the volume up to 2,000 mL.

**BLEEDING**

A bloody effluent (drainage) may be observed occasionally, especially in young, menstruating women. (The hypertonic fluid pulls blood from the uterus, through the opening in the fallopian tubes, and into the peritoneal cavity.) Bleeding is common during the first few exchanges after a new catheter insertion because some blood exists in the abdominal cavity from the procedure. In many cases, no cause can be found for the bleeding, although catheter displacement from the pelvis has occasionally been associated with bleeding. Some patients have had bloody effluent after an enema or from minor trauma. Invariably, bleeding stops in 1 to 2 days and requires no specific intervention. More frequent exchanges during this time may be necessary to prevent blood clots from obstructing the catheter.

**LONG-TERM COMPLICATIONS**

Hypertriglycerideremia is common in patients undergoing long-term peritoneal dialysis, suggesting that this therapy may accelerate atherogenesis. Despite this, the use of cardioprotective medications is relatively low, and many patients have suboptimal blood pressure control. Given the high burden of disease in these patients, beta-blockers and angiotensin-converting enzyme inhibitors should be used to control hypertension or protect the heart; the use of aspirin and statins should be considered. In general, health care providers need to be better educated in this area of dialysis management (Tonelli et al., 2001).

Other complications that may occur with long-term peritoneal dialysis include abdominal hernias (incisional, inguinal, diaphragmatic, and umbilical), probably resulting from continuously increased intra-abdominal pressure. The persistently elevated intra-abdominal pressure also aggravates symptoms of hiatal hernia and hemorrhoids. Low back pain and anorexia from fluid in the abdomen and a constant sweet taste related to glucose absorption may also occur.

Mechanical problems occasionally occur and may interfere with instillation or drainage of the dialysate. Formation of clots in the peritoneal catheter and constipation are factors that may contribute to these problems.

**Acute Intermittent Peritoneal Dialysis**

Indications for acute intermittent peritoneal dialysis, a variation of peritoneal dialysis, include uremic signs and symptoms (nausea, vomiting, fatigue, altered mental status), fluid overload, acidosis, and hyperkalemia. Although peritoneal dialysis is not as efficient as hemodialysis in removing solute and fluid, it permits a more gradual change in the patient’s fluid volume status and in waste product removal. Therefore, it may be the treatment of choice for the hemodynamically unstable patient. It can be carried out manually (the nurse warms, spikes, and hangs each container of dialysate) or by a cycler machine. Exchange times range from 30 minutes to 2 hours. A common routine is hourly exchanges consisting of a 10-minute infusion, a 30-minute dwell time, and a 20-minute drain time.
Maintaining the peritoneal dialysis cycle is a nursing responsibility. Strict aseptic technique is maintained when changing solution containers and emptying drainage containers. Vital signs, weight, intake and output, laboratory values, and patient status are frequently monitored. The nurse uses a flow sheet to document each exchange and records vital signs, dialysate concentration, medications added, exchange volume, dwell time, dialysate fluid balance for the exchange (fluid lost or gained), and cumulative fluid balance. The nurse also carefully assesses skin turgor and mucous membranes to evaluate fluid status and monitor the patient for edema.

If the peritoneal fluid does not drain properly, the nurse can facilitate drainage by turning the patient from side to side or raising the head of the bed. The catheter should never be pushed in. Other measures to promote drainage include checking the patency of the catheter by inspecting for kinks, closed clamps, or an air lock. The nurse always monitors for complications, including peritonitis, bleeding, respiratory difficulty, and leakage of peritoneal fluid. Abdominal girth may be measured periodically to determine if the patient is retaining large amounts of dialysis solution. Additionally, the nurse must ensure that the peritoneal dialysis catheter remains secure and that the dressing remains dry. Physical comfort measures, frequent turning, and skin care are provided. The patient and family are educated about the procedure and are kept informed of progress (fluid loss, weight loss, laboratory values). Emotional support and encouragement are given to the patient and family during this stressful and uncertain time.

**Continuous Ambulatory Peritoneal Dialysis**

CAPD is a form of dialysis used for many patients with ESRD. CAPD is performed at home by the patient or a trained caregiver, who is usually a family member; the procedure allows the patient reasonable freedom and control of daily activities (Chart 44-10).

**UNDERLYING PRINCIPLES**

CAPD works on the same principles as other forms of peritoneal dialysis: diffusion and osmosis. Less extreme fluctuations in the patient’s laboratory results occur with CAPD than with intermittent peritoneal dialysis or hemodialysis because the dialysis is constantly in progress. The serum electrolyte levels usually remain in the normal range.

**PROCEDURE**

The patient performs exchanges four or five times a day, 24 hours a day, 7 days a week, at intervals scheduled throughout the day (before meals and bedtime). After infusing the dialysate into the peritoneal cavity through the catheter (over about 10 minutes), the patient can fold the bag and tuck it underneath the clothing during the dwell time. This provides the patient with some freedom and reduces the number of connections and disconnections necessary at the catheter end of the tubing, thereby reducing the risk of contamination and peritonitis.

The longer the dwell time, the better the clearance of middle-sized molecules. It is thought that these molecules may be significant uremic toxins. At the end of the dwell time, the dialysate is drained from the peritoneal cavity by unfolding the empty bag, opening the clamp, and placing the bag lower than the abdomen near the floor. This allows the peritoneal fluid to drain out by gravity. When drainage ends, the patient repeats the procedure by spiking a new bag containing dialysate and infusing the solution into the peritoneal cavity. Other systems are available that allow the catheter to be clamped, disconnected, and capped, thus allowing the patient freedom from wearing an empty dialysate bag. Before the next exchange, however, an empty drainage bag must be attached to permit drainage of the dwell solution.

**Chart 44-10 • ASSESSMENT**

**Assessing Suitability for CAPD**

Although CAPD is not suitable for all patients with end-stage renal disease (ESRD), it is a viable therapy for those who can perform self-care and exchanges and who can fit therapy into their own routines. Often, patients report having more energy and feeling healthier once they begin CAPD. Nurses can be instrumental in helping patients with ESRD find the dialysis therapy that best suits their lifestyle. Those considering CAPD need to investigate the advantages and disadvantages along with the indications and contraindications for this form of therapy.

**Advantages**

- Freedom from a dialysis machine
- Control over daily activities
- Opportunities to avoid dietary restrictions, increase fluid intake, raise serum hematocrit values, improve blood pressure control, avoid venipuncture, and gain a sense of well-being.

**Disadvantages**

- Continuous dialysis 24 hours a day, 7 days a week

**Indications**

- Patient’s willingness, motivation, and ability to perform dialysis at home
- Strong family or community support system (essential for success), particularly if the patient is an older adult
